**The Quantity Theory of Money Revisited:
The Improved Short-Term Predictive Power of
Household Money Holdings with
Regard to prices**

Jean-Charles BRICONGNE

The quantity theory of money revisited: The improved short-term predictive power of household money holdings with regard to prices¹

Abstract:

This article analyses the predictive power of household money holdings with regard to prices or current aggregates (consumption and disposable incomes) over the short term (i.e. over one quarter), as compared with that of other explanatory variables, namely unemployment and total monetary aggregates.

Regardless of the approach used, in the short term, household holdings exhibit a comparative advantage over unemployment and total monetary aggregates. The gain in terms of RMSE compared to a simple autoregressive equation is often at least 10%. This is consistent with the quantity theory of money, which holds that there should be a fairly direct link between money and consumption with a limited lag.

In the longer run (12 quarters), unemployment exhibits better forecasting properties than household money holdings, which is consistent with the findings of Stock & Watson (1999).

As a by-product, this paper also shows that flows of funds can be used to calculate good proxies of total monetary aggregates, such as M3, or other aggregates such as MZM, which may also have interesting predictive properties.

On the whole, using Divisia aggregates does not improve forecasting properties, unlike the addition of revolving credits to the usual aggregates, especially for countries such as the United States where this type of credit is significant.

This article reflects the views of the author and not the position of its institutions.

I. Introduction

This article reexamines the potential link between money and prices (or alternatively between money and the current values of aggregates such as consumption or disposable income), by revisiting the fundamental definition of the quantity theory of money, in which money supply should be concentrated solely on household money holdings.

To do this, we use available data, mostly on flows of funds, to construct proxies of household money holdings and then compare the predictive power of these indicators with benchmarks such as total monetary aggregates and unemployment.

In theory, there is a link between money supply and consumer prices

The quantity of money circulating M , with velocity V , enables a volume T of transactions to be carried out, at a price level P . The accounting relationship thus obtained is: $MV=PT$ (1).

The first person to write this formally was Irving Fisher (1911), who turned the accounting relationship into a causal one: if one supposes that V is constant, at least in the short term, given that it depends on structural factors and consumer habits, and that transaction volumes do not depend on monetary factors, then if the quantity of money increases, the general level of prices also increases in the same proportion.

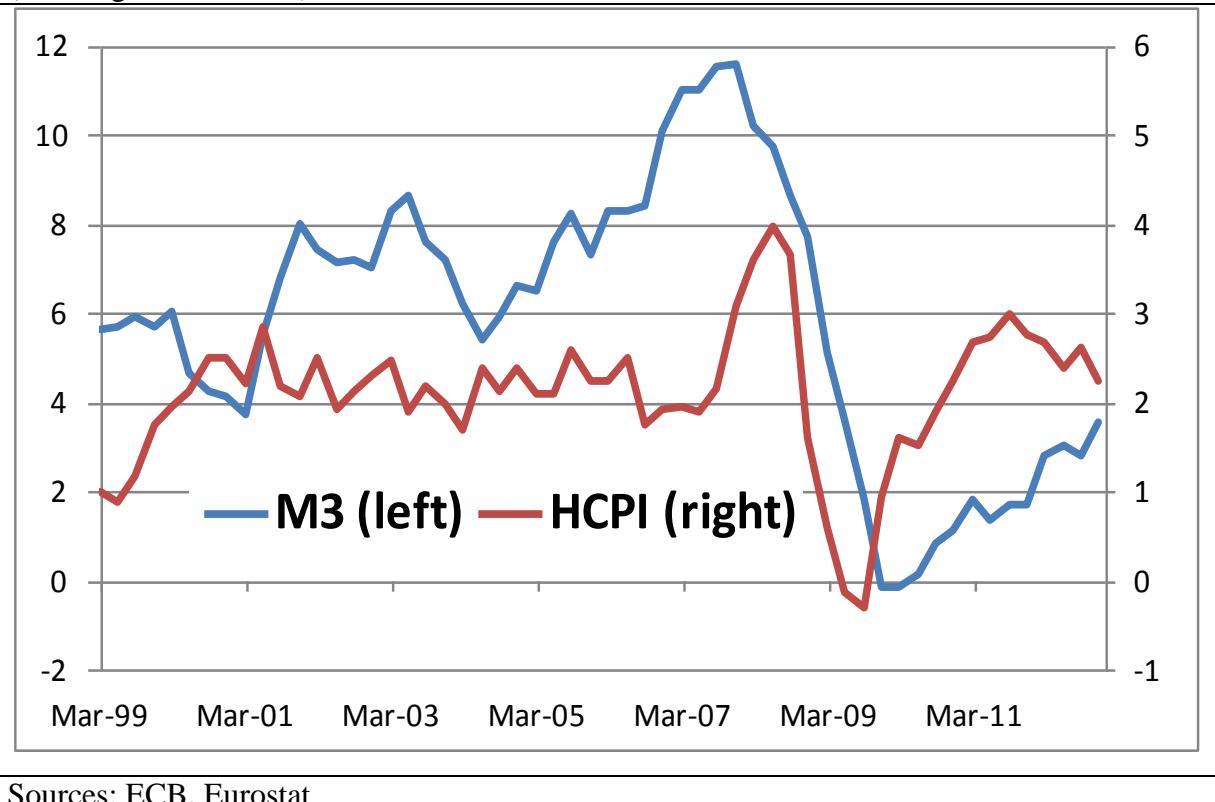

A subsequent article by K. Cartensen (2007) seems to confirm the role of monetary growth in inflation on at least three levels:

- monetary growth has the advantage of providing exogenous information, unlike past inflation which only provides endogenous informational content. Taking monetary growth into account is thus useful in giving an indication of future inflation.
- the long-term relationship between monetary growth and inflation has remained stable over the past few decades.
- from the beginning of the 90s' onwards, monetary growth can be taken into account in forecasting models without creating any significant instability.

The link between the evolution of money and prices seems to have diminished

Using a quantitative-like relationship where all terms are liable to change, the ECB has established an indicative goal for monetary growth of 4.5% per year. This goal has consistently been exceeded in the euro area since May 2001, and increasingly so since May 2004 (with a peak of close to 12% in 2007), with no noticeable impact on prices (see graph below).

Graph 1 – Euro area: evolution of M3 (left-hand scale) and of HCPI (harmonised consumer price index, right-hand scale)
(annual growth rate, %)

Sources: ECB, Eurostat

A study by the OECD (2007) seems to confirm that, while the predictive power of monetary aggregates was satisfactory in the period 1995-2000, since 2000 this has no longer been the case. These conclusions should nevertheless be regarded with caution as major events such as the launch of single currency in Europe may have introduced some prolonged disruptions.

The apparently diminishing relationship between money and prices is confirmed by the fact that the ECB makes less and less reference to its “first pillar” of monetary policy, that is M3. The Federal Reserve has even stopped publishing M3, on the basis that its usefulness can no longer be justified.

Different approaches have been considered in the literature to try to reconcile evolutions in money and prices

Using the quantity theory of money as a starting point, various different approaches have been developed to try to reconcile evolutions in money supply and in prices.

One type of approach is to vary the scope of monetary assets taken into account by adding in assets such as bonds and equity funds (cf. Orphanides et al. (1994) or Collins and Edwards (1994)), or considering different assets weighted by yields, corresponding to different velocities, giving a Divisia approach.

Instead of adding assets to the usual monetary aggregates, other methods consider only part of these aggregates and eliminate certain asset categories. This is the case with the MZM aggregate calculated by the Fed, and which is also transposed to other countries/zones in this article, using mainly flows of funds. This aggregate consists of money with zero maturity. It measures the supply of financial assets redeemable at par on demand. Unlike M3, in the case of the US, it does not include time deposits.

A second type of approach in the literature is to question the assumption that velocity is constant. Since the quantitative approach supposes that the velocity of money is stable in the short run, it may in fact vary over the medium/long term, as suggested by Bordes et al. (2007).

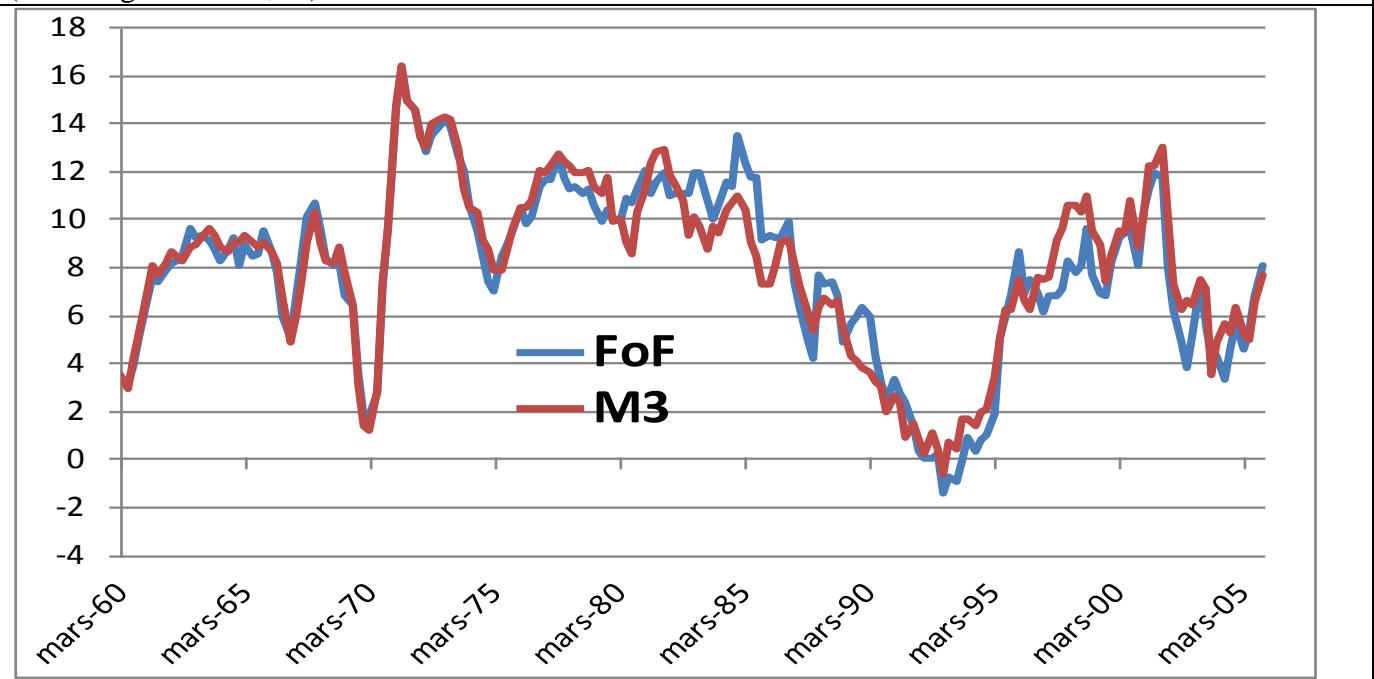

Another type of approach is to consider that, if the quantity theory of money relates to household consumption, then the only money holdings taken into consideration should be those of households, and not of those of non-MFIs (MFIs: monetary and financial institutions, which create money). It is this latter approach that is examined in this article, by comparing the forecasting properties of household money holdings to that of total aggregates, in the short (one quarter) and in the longer (twelve quarters) run.

II. Financial accounts/flows of funds can be used to build monetary aggregates for money holders and households

As a by-product, we also confirm in this article that aggregates built with financial accounts/flows of funds are similar to published monetary aggregates and have comparable forecasting properties, over the period where these two kinds of aggregates are built/are available.

For the US, we considered the period 1973Q1-2006Q1 using Drake & Mills (2005). The results in Appendix 3 confirm that the published monetary aggregate M3 gives very close results to the corresponding series built with flows of funds.

USA: growth rate of M3 published by the Fed (“M3”) and calculated with flows of funds (“FoF”)
(Annual growth rate, %)

Source: Federal Reserve, Flows of Funds, calculations of the author

For France, using the period 1977Q4-1998Q4 (because since the launch of the euro, monetary aggregates are no longer published by country: only country contributions to the evolution of euro area monetary aggregates are published), we also find quite similar forecasting performances for published total M1 and for flows-of-funds-derived M1 on the one hand, and for published total M3 and flows-of-funds-derived M3 on the other hand (RMSE may even be smaller for flows-of-funds-derived aggregates).

For the construction of variables: cf. Appendix 1.

III. Regardless of the monetary aggregate considered, household holdings usually exhibit better statistical properties for short-term forecasting than the usual monetary aggregates and unemployment

Where possible, we consider four or five monetary aggregates which have a similar definition in each of the countries under review:

- M1: in all countries, this includes currency holdings and current accounts;
- M2: in addition to M1 assets, this aggregate usually includes interest-bearing deposits, redeemable at notice or short-term. The US has an alternative definition which includes savings accounts and small time deposits, both of which are mainly held by households;
- M3: M3-M2 assets are mostly short-term bills issued by monetary and financial institutions and shares in money market funds (institutional money market funds in the US);
- M4: this aggregate is only taken into account in the case of the United Kingdom. M4-M3 are mostly assets issued by non-financial corporations;
- MZM: this is only calculated by certain countries, such as the US, and includes monetary assets which are immediately available, making it roughly equal to M2 minus small time deposits plus shares in (institutional) money market funds.

These monetary aggregates are used to try to forecast the evolution of different variables: consumer price indexes, consumption in value terms and gross available income in value terms. We may also consider the consumption deflator as a robustness check.

To assess the forecasting power of the variables, we use two alternative methods.

A. Drake & Mills (2005) model

The first model is an adaptation of the one used by Drake & Mills (2005) (which itself refers to Stock & Watson (1999)), who tested batteries of indicators, including monetary aggregates, and concluded that their forecasting properties are low. This assertion may be true for total aggregates but, as will be shown, it is no longer true for household aggregates.

The reference forecasting model used in Drake & Mills (2005) is as follows:

$$\pi_{t+k}^k = a + \sum_{i=1}^4 b_i \pi_{t-i}^k + \sum_{i=1}^4 c b_i x_{t-i}^k + e_{t+k}$$

Where $\pi_t^k = \left(\frac{4}{k}\right)(p_t - p_{t-k})$ is k-period inflation and x_t^k is a similarly defined growth rate of the indicator aggregate.

In order to analyse the forecasting results in the short term, we take inflation between (t-k) and t as a variable rather than between t and (t+k). k is taken to be equal to twelve quarters (which allows us to neutralise seasonal effects and avoids overlaps between the lagged variables which would have occurred with k=4, on the right-hand side).

In addition to total and households' monetary aggregates, we consider unemployment as a benchmark, both in terms of level and growth rate.

United States

As can be seen in Appendix 2, for both the periods 1998Q4-2012Q4 (where we can test the aggregate "M1 households + revolving credits households, Divisia") and 1973Q1-2012Q4, we find the following stylised facts:

- household money holdings nearly always produce the results with the smallest RMSE, outperforming both unemployment and the usual monetary aggregates;
- compared to purely autoregressive models, the gains in terms of RMSE are around 10% ;
- including revolving credit in the calculations often improves forecasting properties.

United Kingdom

Over the period 2002Q2-2013Q1, the different aggregates produce relatively similar results in terms of consumer price index growth. However, on the whole, total aggregates perform better, with M1 and M4 Divisia ranking first and second, followed by M1 households and M2.

Given the short time period under review, however, robustness checks would need to be carried out over a longer time span.

Results for the other two variables to explain (current consumption growth and current gross disposable income growth) vary more widely according to the aggregate used, with household money holdings producing by far the best outcome. At best, gains in terms of RMSE range between 25% and 40% compared with purely autoregressive models.

France

Over the period 1993Q1-2012Q4, regardless of the variable to explain (consumer price index growth, current consumption growth and current gross disposable income growth), the best indicators in terms of RMSE all refer to household money holdings.

The best indicators enable a gain of around 10% in RMSE compared with purely autoregressive models.

Euro area

Given that euro area statistics are only available for a short time period, due to the relatively recent launch of the euro, results remain to be confirmed over a longer period.

Between 2001Q3 and 2012Q4, total aggregates perform better than household money holdings for consumer price index growth, consumption deflator index growth and, to a lesser extent, for current consumption growth, although the differences in RMSE are fairly limited.

However, the gain is more significant (almost one third compared to purely autoregressive models) for M3 household holdings (with or without revolving credit) when used as an indicator for gross disposable income growth.

Summary of results for the four countries/zones under review

The results obtained for individual countries/zones can be summed up as follows:

- Household money holdings enable a gain of at least 10% in terms of RMSE compared to purely autoregressive models.
- Household money holdings usually outperform unemployment and total aggregates.
- Results are better for current consumption growth and current gross disposable income growth than for consumer price index growth. **In the case of current consumption growth compared to consumer price index growth, this can be explained by reference to the quantity theory of money, which deals with current expenses rather than just price indexes.**

B. Stock & Watson (1999) model

The second method is the one developed by Stock & Watson (1999), used over the short term (one quarter) and the longer term (twelve quarters).

United States

Over a one-quarter horizon, the best forecasts are almost always obtained with household money holdings, except for current consumption growth, where the results for M1 household holdings are very similar to those obtained using unemployment.

Over a twelve-quarter horizon, the results are much less biased towards household money holdings. However, flows-of-funds-derived M3 displays fairly good results on the whole.

United Kingdom

Although household holdings perform poorly over a one-quarter horizon for consumer prices and consumption deflators, their performance is much better for current disposable income and current consumption.

Over a twelve-quarter horizon, the results are quite similar and do not exhibit any obvious comparative advantages in favour of unemployment, total money aggregates or household holdings. However, as with the Drake & Mills (2005) model, the short time period under review means there would be a need for robustness checks over a longer time span.

France

Over a one-quarter horizon, the best results are obtained with household money holdings, except in the case of current consumption growth, for which unemployment outperforms money indicators.

Over the twelve-quarter horizon, unemployment outperforms money indicators most of the time, and household money holdings lose their relative advantage (except in the case of the consumption deflator). These results are consistent with Stock & Watson's findings (1999) for the US, which show that, over the medium term, money aggregates perform rather poorly.

The results are also consistent with the quantity theory of money, which is an accounting relationship and should work in the short term, but not necessarily in the longer term: there is no reason why households should hold money for their private consumption several years in advance.

Euro area

The results over a one-quarter horizon show quite good forecasting properties for household money holdings (with M3 and MZM) and also for total MZM, which would suggest it is better to consider sectoral holdings, but also to consider another aggregate, namely MZM. Yet, even if the period is somewhat longer than with the Drake & Mills (2005) model, due to the fact that working with one-quarter growth rates includes more quarters than using twelve-quarter growth rates, the period remains rather short, and the results may vary by few points. This is particularly true for the period under review as it includes the current financial crisis.

IV. Conclusion

We compared the performance of different kinds of explanatory variables: (unemployment, total monetary aggregates and household money holdings) in forecasting the evolution of prices (consumer prices or consumption deflators) or current aggregates (private consumption and private disposable incomes).

Regardless of the approach used, in the short term, household holdings exhibit a comparative advantage over unemployment and total aggregates. The gain in terms of RMSE compared to a simple autoregressive equation is often at least 10%. This is consistent with the quantity theory of money, which holds that the link between money and consumption should be quite direct with a limited time lag.

Over the longer run, the quantity theory of money, which is an accounting relationship rather than an economic-based relationship, loses its statistical properties and is outperformed by unemployment. This is consistent with Stock & Watson's findings (1999).

On the whole, household holdings can be calculated directly using flows of funds, but these calculations may require some approximations. Further detail may help to make the calculations more precise and improve the forecasting properties of household holdings even further.

A by-product of this article is that flows of funds can also be used to calculate good proxies of total monetary aggregates, such as M3, or other aggregates such as MZM, the predictive power of which may be significant.

Using Divisia aggregates rarely improves forecasting properties, unlike adding revolving credits to the usual aggregates, especially for countries such as the US where they are significant.

Appendix 1: construction of datasets

United States

We used data on flows of funds, which are sufficiently detailed to enable the construction of money holdings with a corresponding level of detail to M1, M2 and M3.

The main problem was how to split time deposits between small-denomination time deposits, belonging to M2, and other time deposits, belonging to M3.

Thus, to construct M2 household holdings, for instance, we used household currency holdings and checkable deposits, combined with M2-M1, as the Fed has indicated that this difference is almost entirely held by households.

M1 and M2 are updated but, as M3 is no longer available, a proxy was calculated using flows of funds.

United Kingdom

As in the case of the US, flows of funds were used to build money holdings.

The biggest problem was how to split “other deposits” between M2 and M3 for households. Since we had no obvious rule for this, we built several series, attributing this kind of deposit entirely to M2 or M3.

Regarding the particular case of M4, which is only available for the UK, the available series of M4, M4 Divisia and M4 held by households were used.

Moreover, since there may be some breaks caused by changes in scope, impacting stocks and not flows, where possible, we tested both stocks and cumulated flows.

France

French flows of funds (“*comptes financiers trimestriels*”) are sufficiently detailed to get money holdings directly.

The only problem was to get the corresponding sector holding the short-term debt securities, in order to keep only MFI issuers. Since this detail was not available, we took the total amount of short-term debt securities, regardless of the issuer.

Since monetary aggregates have no longer been available for national members of the Eurosystem since the launch of the euro, these aggregates have been proxied using flows of funds.

We checked that the evolution of flows-of-funds-derived aggregates and aggregates available until 1998Q4 are highly correlated.

Euro area

Some series are available for household money holdings. Other series were calculated using flows of funds, where possible.

Use of revolving credits and total short-term debt securities, regardless of the issuer

Since revolving credit is often used directly to consume, without appearing in deposits, we tested the inclusion of revolving credits for each aggregate.

The inclusion of these credits in the assets of households may be legitimate, in the sense that it is indeed used by a household to consume thereby replacing another liquid asset which becomes available for another transaction.

Moreover, when considering households on their own, there is no netting of this means of payment against companies granting this type of credit.

By the same token, it is also legitimate to take into account the short-term debt securities in the assets of households, and not only those issued by MFIs. This can be understood by comparing these securities with the money holdings of non-MFIs: when a non-financial company issues a debt security which is bought by a household, there is a form of liquidity transfer from the household to the company and the impact is globally neutral for non-MFIs.

One last argument in favour of including revolving credit is that the Fed already includes travellers' checks in M1 ("Data for the nonbank traveller's checks component of M1 are reported by six nonbank issuers of traveller's checks as of the last business day of each month. Traveller's checks issued by banks are included in the demand deposit component of M1.").

When revolving credits are used to build Divisia indexes, we regard them as having a negative yield, equal to the interest rate.

Appendix 2: Tables of results

Drake & Mills (2005) model

United States (1998Q4-2012Q4)

In the case of the US, we first considered the period 1998Q4-2012Q4 because we calculated a series of household M1 holdings plus revolving credit, according to a Divisia method, using revolving credit rates that were only available over a limited period.

We also considered the period 1973Q1-2012Q4 (see next page), dropping this variable, to obtain results over a longer period, as a robustness check of the benefit of using household holdings.
