Assessing proglacial sediment sources evolution of three catchments using the index of connectivity (IC), Plan de l’Aiguille, Chamonix, France

Introduction

Glacier connexion with stream channel has been evolved since the end of the Little Ice Age. We here investigate a geostatistic approach based on the connectivity index (IC) and glacier shapes extensions (around 1820, 1971 and 2008) in order to assess the spatial sediment connectivity.

The goal of our study is to identify and quantify sediment sources for proglacial streams for these three dates.

We applied the method on three proglacial streams located at the foot of the Aiguille du midi ("plan de l’Aiguille"). The study streams are originating from cirque glaciers with massive morainic bastions.

Results

We used the method on three proglacial streams located at the foot of the Aiguille du midi ("plan de l’Aiguille"). We observe that the streams are originating from cirque glaciers with massive morainic bastions.

The results show that the proglacial sediment sources have evolved since the Little Ice Age. The method reveals that the sediment sources have narrowed as the glaciers retreated.

The oldest picture found (1863) shows the Glacier des Pellerins and a small glacier located SW. IC results are thus underestimated, especially for the latter one.

Main limits of the method:
- It implies the hypothesis that topography has not changed since the LIA.
- The LIDAR DEM does not cover the entire stream catchments. It doesn’t include the upper part of the Glacier des Pellerins and a small glacier located SW. IC results are thus under-estimated, especially for the latter one.
- Glacier extension accuracy.

Results checks

The interpretation of the large sets of photogra- phs available in Chamonix allows checking our results, also helped with airborne photographs.

Airborne photographs show that the Glacier des Pellerins proglacial area is still drained contrary the two other glaciers. In 2008, Grépon and Blaitière headwaters are almost inactive and moraines are vegetation-covered. It confirms the narrowing sediment sources.

General interpretation

- IC counts have strongly declined for all the streams, mainly because of the decreasing area supplied by glacier water.
- Highest values are consistent with the stream channels that are relatively stable.
- LIA Gaussian distribution is consistent with the outer moraine supply.

Specific interpretation

- For Blaitière and Grépon streams, a threshold appears between the LIA and 1971. The glacier doesn’t overflow the moraine crest anymore. The outer moraine flank is thus not supplied by the glacier melt water. Sediment sources are contracting into the morainic basin.
- IC has declined more progressively for the Favrandes catchment because of the lack of real terminal moraine. The proglacial area is still efficiently drained.

Conclusion

- This study shows that Plan de l’Aiguille glaciers retreat implies a more or less sudden disconnection from glacial sediment sources to alluvial fan. IC decreasing is confirmed by the analyses of old picture and historical floods archive records.
- The levelled disconnection is directly linked to the glacier mor- phologies.

Method

IC (Cavalli and al, 2013) is based on high resolution (LIDAR) DEMs. It is calculated with several topographic indexes (slope, residual topography, contributing area and distance to the outlet) integrated into a downslope and an upslope components. We isolated the contributing area (A) which could be supplied by glacier melt water with the glacier spatial extent at different dates: 1820 (LIA), 1971 and 2008. A lower limit of 0.1 is added to the contributing area to get a realistic flow pattern.

Results give the potential level of sediment connectivity of area which could be supplied by glacier melt water.

Method conclusions and perspectives

Although the method could have bias, results give a specific survey of the evolution of sediment sources and their level of connectivity with the alluvial fan.

This method needs to be applied for other cirque glaciers with full LIDAR cover to confirm the findings.

However the method is not adapted for valley glaciers because of the importance of lateral processes (e.g. lateral moraine erosion) and the morphological activity level (topographic changes are too important).
