Abstract

Container shipping gives a rise of international trade since the 1960s. Based on navigation data start from the mid-1990s to 2016, this paper empirically analyses the spatial pattern of China's international maritime linkages along the “twenty-first-century Maritime Silk Road”. We interpret such evolutionary dynamics in terms of growth, hierarchical diffusion and networking phases. Networking is a new stage of the evolution of the port system, which is approached based on the graph theory, complex network methods and geomatics, the paper discusses the networking's basic characteristics: multi-hub spatial agglomeration, the connection of the network develops across space, functional differentiation and a division of labour appear among ports. Our results show that, while the scope of China's maritime linkages had expanded overtime, more foreign ports become connected to the “Maritime Silk Road”. In addition, the external linkages of domestic ports tend to be dispersed, reflecting upon the decline of Pearl River Delta ports and the rise of Yangtze River Delta ports, with mixed evidence for the Bohai Rim region. Lastly, the analysis underlines the emergence of a polycentric shipping system, from the Hong Kong dominance to the more diversified Shanghai/Ningbo/Shenzhen configuration. Academic and managerial implications are included.

Keywords: Maritime Silk Road; shipping system; spatial pattern; networking

1. Introduction

“The Belt and Road” is referred to the “Silk Road Economic Belt” and “twenty-first century Maritime Silk Road” (hereafter called “Maritime Silk Road” or MSR). The Belt and Road is aimed at borrowing the historical legacy of the Ancient Silk Road, in order to actively develop economic partnerships with countries along it. The MSR is a sea channel for economic and cultural exchanges between China and other parts of the world. The MSR not only limits to the ASEAN, but also aims to enhance exchanges with other neighbouring countries and regions, to develop a strategic cooperative economic zone facing the South China Sea, the Pacific and India oceans, and to focus on the integration of economy and trade with Asia, Europe and Africa as a long-term development goal. MSR covers more than 60 countries, now accounting for more than 35% of the world's merchandise trade and around 30% of global GDP. MSR would contribute 80% of global GDP growth by 2050 (HKTDC, 2017). In principle, the Belt and Road has demonstrated 5 core areas of

cooperation pertaining to policy coordination, network connectivity, trade and investment, financial integration and cultural exchange. Regional cooperation and competitiveness will be significantly enhanced (HKTDC, 2017).

The proposed paper takes the so-called MSR strategy proposed by the Chinese government as an opportunity to push further the understanding of China's changing maritime position globally. Although Chen and Hu (2016) analysed the shipping networks of South-east-Asian route along MSR, while Zhang, Huang, and Hu (2017) evaluated the hub position of the East Asian port under MSR. A significant contribution was provided by Tran and Haasis (2014) in their empirical analysis of liner shipping networks along the so-called East–West corridor between 1995 and 2011 even if their studies considered connectivity patterns between main regions as nodes, not port nodes. Overall, other previous studies of the MSR are primarily based on qualitative analyses published either in media reports or other press releases, to such an extent that a more objective and quantitative overview remains a seriously ignored. In addition, several reports published by either international or local organisations as well as the press well covered and developed the significance of the MSR concept for Western countries and ports. Yet, a comprehensive, quantitative analysis of the spatial evolution of the MSR before, during, and after its official announcement remains missing in the literature. Chinese companies such as COSCO Shipping, China Merchants Group, SIPG are increasingly involved in port projects of MSR. It is important to find out which ports and routes are vital to China over the past 10–20 years and which ports will generate good development potential in the future. Pushing further our understanding of the current patterns and challenges of the emerging MSR, we can provide a theoretical and empirical basis upon which a better overview can be provided in order to enhance cooperation and integration along such a key twenty-first century trunk line.

This paper is split into six main sections. To begin with, an introduction is given in Section 1, Section 2 conducts a literature review about existing academic works having looked at the MSR through various quantitative methods. After that, Section 3 shows the data and methodology. We are based on shipping linkages among world ports to analyse a network within the MSR region. Main results are to describe evolutionary stages and characteristics of such a network and spatial pattern in Sections 4 and 5, respectively. Finally, a brief discussion and conclusion are provided in Section 6.

2. Literature review

In the 1950s, researches on shipping systems still remained at an infant stage, as port geographer mainly focused on individual ports, port cities and countries without paying much attention to formalised inter-port relationships (Rimmer, 1967). Since the late 1960s, container shipping has been achieved important milestones such as intermodalism, technological innovations and international trade facilitation (Lau, Ng, Fu, & Li, 2013). Yet, both Chinese and foreign scholars gradually improved their understanding of shipping systems from different perspectives. Some theoretical aspects were outlined by pioneering models of port system evolution in developing countries (Taaffe, Morrill, & Gould, 1963), giving birth to a six-stage model leaning towards concentration on one main gateway. Later on, Hayuth (1981) updated such a model through five stages based upon the evolution of U.S. container ports. At the more local level, other models were proposed, such as those of Bird (1971)'s Anyport model, Hoyle (1989)'s evolutionary model of the port-city interface, and Notteboom and Rodrigue (2005) updated the original model by incorporating dry ports and offshore hubs. Throughout Western studies, most empirical researches paid attention to the geographic distribution of specific ocean carriers (e.g.

Fremont, 2007), to the partial overlap between carrier networks and terminal operator networks (Parola & Veenstra, 2008), and to the topological features of regional and global shipping networks (e.g. Ducruet, Lee, & Ng, 2010; Ducruet & Notteboom, 2012). Another approach had been to provide a supply chain approach to shipping networks (Lam & Yap, 2011), with useful and concrete discussions about the design, logistical and time constraints of such networks (Imai, Shintani, & Papadimitriou, 2009; Karsten, Pisinger, Ropke, & Brouer, 2015, 2016) in the more “operations research” field. Yet, one central question of the proposed paper is whether such global approaches apply to the particular case of China, Chinese ports, and their related shipping networks in a context of gradual expansion in the last decades and in the near future.

China's container shipping activity began in the late 1970s. Domestic scholars conducted relevant research since the 1990s and mainly in the mid-2000s to unravel China's container transportation network, its position in the global shipping networks (in terms of physical flows), and within the networks of global transport firms (in terms of company organisations). The first group of studies takes China as the core subject of investigation, questioning its maritime connectivity in various ways (Comtois & Wang, 2003; Rimmer & Comtois, 2005).

Some studies have provided an analysis of the whole Chinese port system in terms of port throughput dynamics (Pan, Cao, Liang, & Wei, 2014; Wang & Ducruet, 2013). Song and Cui (2014) believed that the big jump of China's container throughput has resulted mainly from massive investment in terminal infrastructure and significant improvement in their operation and management. Some scholars focused on port integration mechanisms (Wang, Ducruet, & Wang, 2015). Some researchers also studied about the regional port systems or individual ports, sometimes shifting the focus towards the whole container transport network or the relationships between ports and their hinterlands in various regions, such as the Bohai Rim, the Yangtze River Delta, and the Pearl River Delta (Cao, Jiang, Chen, Wei, & Shuangbo, 2015; Liu, Wang, & Yip, 2013; Wang, 2007; Wang, Wang, & Ducruet, 2012; Wang & Hong, 2016; Wang, Zhang, & Ye, 2017). Pioneer works at the local level include more qualitative analyses of the vital role of Hong Kong for in South China's port modernisation and connectivity (Song, 2002; Wang, 1998).

Other scholars preferably insisted on the influence of global shipping networks configurations on mainland Chinese ports at the level of large world regions (Xu, Li, Shi, Zhang, & Jiang, 2015). Ducruet, Cuyala, and El Hosni (2018) underlined barrier effects in the global maritime network linking cities of the world in the case of China.

The above studies have demonstrated the influence of global shipping networks on the development of local ports, mainly concentrating on the spatial pattern of port systems, shipping networks and the location and function of main hub ports. However, as far as

China is concerned, the existing research in this area is far from sufficient. Studies of the container handling industry, using the latest data from individual terminals, is still scarce up to date, especially when it comes to the precise understanding of the position of individual Chinese ports at the global or regional (transnational) level, except from the study by Wang and Ng (2011) about the maritime forelands of Chinese ports.

Lau, Ducruet, Ng, and Fu (2017) reviewed 294 research papers to highlight the emergence of maritime network design has placed the importance of contemporary research in the past two decades. Maritime network analysis from a quantitative perspective, and especially about the MSR region, still remains much limited and fragmented across the academic spectrum (Ducruet, 2015). Ducruet and Notteboom (2012) used the single linkage analysis method to reveal the changing spatial pattern of the so-called “nodal regions” composing the global container shipping network. They particularly showed that Hong Kong was at the centre of the largest nodal maritime region in 1996, expanding across the Pacific and up to the African and European shores, while it expanded dramatically in 2006 as it comprised nearly the whole of Africa. Other quantitative works on the global container shipping network hinted at a number of trends but with large regions as the unit of analysis, such as in the works of Lau et al. (2017), Xu et al. (2015) and Li, Xu, and Shi (2015), confirming the growing importance and centralisation upon East Asia. Providing a more detailed overview of the evolution of this particular MSR shipping system is thus the main objectives of our research.

3. Data and methodology

3.1. Data

The countries and regions composing the MSR represents a key part of China's international maritime transport. Since the MSR is an open and cooperative networks, it shows no precise spatial definition and geographic delineation (Figure 1). It is often described as a corridor starting at China's coastal ports and further extending up to Europe through the South China Sea and the Indian Ocean. This study thus includes all ports belonging to border countries and regions along this route (see Figure 2; Wang & Hong, 2016).

The data used in this paper are collected from China Shipping Weekly and Lloyd's List Intelligence (LLI). China Shipping Weekly gives a comprehensive container flows between China (including Taiwan except in 1995) and the rest the world. This weekly magazine was founded in 1993 as the authoritative shipping information source. Also, it was managed by the National Development and Reform Commission and sponsored by the China Communications and Transportation Association. Key information includes container ship's destination port, departure and arrival time, vessel name and voyage, to name but a few. Based upon this source, it was possible to construct a container shipping system composed of nodes (ports) and edges (routes). It includes a total of 133, 117, 145 container ports in 1995, 2005, 2015, respectively.

The same methodology was applied to a complementary source obtained from LLI, which condenses most of the world containerships' daily movements for the last decades. A good example of using such data is the recent study by Ducruet and Wang (2018) of China's global shipping connectivity since the late nineteenth century. We

Figure 1. Maritime Silk Road geographical map. Source: HKTDC (2017).

extracted the flows that occurred between China and all the ports situated along the MSR up to North Europe in order to map these flows at different points in time, namely 1997, 2001, 2005, 2009, 2013 and 2016. It is important to notice that LLI flow data had been incorporated into a geovisualisation tool made by the authors to map their volume and distribution by link and by port (for more information about this tool, see Ducruet & Bunel, 2017). The cartography of the MSR is provided in this article based on a new Geographic Information System entitled Geoseastems, which recently allowed mapping the spatial patterns of mega-ship traffic around the globe (Ducruet & Berli, 2018). It results

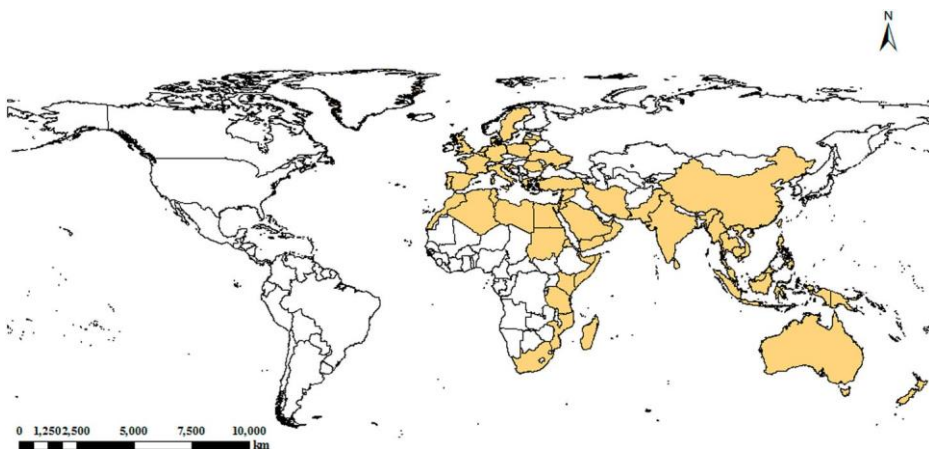

Figure 2. The spatial range of MSR area.

in a collection of maps capable of grasping the essential spatial features of this spatially embedded object between 1997 and 2016. Based on vessel movement data obtained from the world's leading marine insurer Lloyd's List, we assigned weighted inter-port flows to a virtual maritime grid with Twenty-foot Equivalent Units as the unit of analysis. The underlying port-to-port matrix only comprises mainland China ports and Hong Kong, together with their overseas linkages with the ports of the MSR region, based on 2 aggregated months of daily movements each year (i.e. May–June). Domestic flows were ignored but international dynamics were recognised. The port hierarchy as well as the density of flows exhibit both stability and change over the study period. The number of connected ports evolved between 76, 96, 100, 125, 131 and 92 for the last year. In 2016, there was a decreasing number of connected ports due to a shorter time coverage of the data and the time series ends on June 22 instead of June 30.

From the perspective of the route proportion changes between China and MSR area in 1995–2015 (see Table 1), the routes' proportion between China and Southeast Asia and Europe was over 50%. Southeast Asia and Europe are important forelands of China.

3.2. Methodology

3.2.1. Graph-theoretical tools

In the study of spatial flows, the concept of the hub is characterised by the functions of centrality and intermediacy (Fleming & Hayuth, 1994) as well as by processes of agglomeration, diffusion and the integration of the latter two. Since U.S. geographers introduced mathematical tools in the early 1960s, Graph theory is widely used in research studies of spatial networks and flows occurring across space, especially in transport geography (Ducruet & Beauguitte, 2014), especially in transport geography. This paper uses Origin-Destination maritime flow data to identify international maritime hubs and their position in the network by means of several calculations and algorithms. The main steps of the analysis are as follows:

- (1) Build the O-D matrix. Build the O-D matrix X according to the flows between domestic and foreign ports, O as the departure port, D as the terminal port, x_{ij} as the actual number of shipping lines from port i to j . Then, the new matrix Y is obtained by a standardisation process according to the maximum value of x_{ij} :

$$y_{ij} = x_{ij}/\max(x_{ij}), \quad (1)$$

$$0 \leq y_{ij} \leq 1 (i, j = 1, 2, \dots, n),$$

Table 1. The route proportion changes between China and MSR area, 1995–2015.

	1995		2005		2015	
	Line	Proportion (%)	Line	Proportion (%)	Line	Proportion (%)
Oceania	37	7.76	243	10.50	273	6.55
Mediterranean Sea	87	18.24	246	10.63	500	12.00
East Africa	15	3.14	64	2.77	125	3.00
Southeast Asia	104	21.80	573	24.76	1449	34.76
South Asia	28	5.87	165	7.13	253	6.07
Europe	139	29.14	780	33.71	1046	25.10
West Asia	67	14.05	243	10.50	522	12.52

Source: China Shipping Weekly, 1995–2015.

- (2) Calculating process. x_{ij} and y_{ij} both reflect the direct relation between ports in matrix X and Y . In fact, there is an indirect connection between ports. Indirect contact is contained in the node level and needs to be modelled. First, the adjacency matrix Y is constructed, the indirect relation among nodes is weakening with n value is increasing. The indirect connection matrix A is derived according to the following formula:

$$a_{ij} = \sum_{k=1}^n y_{ik} y_{kj} \quad (k = 1, 2, \dots, n), \quad (2)$$

In formula: a_{ij} is the element of the matrix Y^n , y_{ik} is the connection load between node i and k , y_{kj} is the connection load between node k and j . The above formula combines the indirect relation of n terms.

- (3) Calculating equation. Define the element b_{ij} in matrix B is the sum of direct and indirect connections between port i and j , let I as the unit matrix, since the initial data does not have a directed circle, the matrix $(I-A)$ is invertible, that is, there exists an inverse matrix $(I-A)^{-1}$ that represents the number of paths from node i to j , the matrix is calculated by Matlab7.1:

$$B = (I - A)^{-1} - I. \quad (3)$$

3.2.2. Herfindahl-Hirschman index

Concentration, concentration ratio, Herfindahl-Hirschman index (HHI), Lorenz curve and Gini coefficient are commonly engaged in measuring the degree of concentration and dispersion. HHI can accurately reflect the relative size of the major ports in the port system (Pan, Cao, Liang, & Wei, 2013). HHI has the advantages of considering both absolute and relative concentration, while avoiding their respective shortcomings. Although this index is widely employed in the research on container ports, it has some defects such as the influence of sample size on the results. Therefore, this paper adopts a HHI modified by Pan et al. (2013) to measure the concentration and dispersion degree of domestic and international container ports along the MSR. Thus, it can lower the effect of sample size on the calculation results. Its formula is as follows (Pan et al., 2013):

$$H^* = \frac{\sum_{i=1}^n x_{ij}^2 - \frac{1}{n}}{1 - \frac{1}{n}}. \quad (4)$$

The calculation is according to route data in this paper. In the formula, n as the number of ports in the port group or port system, x_{ij} as the number of routes of port i in port group j or port system j , H^* as modified concentration dispersion index for the port group j or port system j . $0 < H^* < 1$. On the one hand, $H^* \rightarrow 1$ implies the routes distribution of the port group or port system tends to be concentrated. On the other hand, $H^* \rightarrow 0$ explains the routes distribution of the port group or port system tends to be dispersing.

4. The evolution of the MSR shipping system

Economic factors, complex shipping networks design and diverse geographical location are the driving forces for the generation and evolution of container ports, notably

international trade patterns (Zheng, Zhang, & Huang, 2017). In accordance with early port system evolutionary models (Hayuth, 1988; Notteboom & Rodrigue, 2005; Rimmer, 1967; Robinson, 1998; Taaffe et al., 1963), the evolution and development of the shipping system along the MSR area can be summarised by the following stages: growth, hierarchy and networking (Wang & Zhu, 2017).

4.1. Growth stage (1980s–1990s)

In this stage, the whole system structure is growing, but the number of ports in the system remains relatively small. A few container ports were gradually became the largest and most central ports after the adoption of the new container technology. Main linkages between central ports and the MSR remained stable, notwithstanding an increase in the number of scheduled links. Linkages between secondary ports and the MSR often occurred through the already established major central ports. The so-called “preferential attachment process” is specific to scale-free networks (see Barabási & Albert, 1999). In the growth stage, domestic routes were mainly concentrated on the Pearl River Delta, with marked differences between North and South in terms of traffic levels and connectivity. Hong Kong was nearby Southeast Asia where it has received benefits from a favourable geographical position, a sound ship registration system and more relaxed and preferential tax policies. To this end, Hong Kong enhanced its main role as a main connector between China and the rest of the world (Wang & Cheng, 2010; Wang & Ducruet, 2013). Most major container seaports in China act as feeder ports towards the Hong Kong hub, while other large mainland Chinese ports had not yet developed and independent from ocean routes. Yet, Shanghai benefitted from its unique geographical advantages such as the interconnection between seaports and Yangtze River ports, and the development and opening of the new Pudong area in Shanghai in 1990. Shanghai has gradually forming a dual system with the Pearl River Delta (Wang & Ducruet, 2012).

4.2. Hierarchical stage (2000s–2010s)

In this stage, a small number of central ports became hub ports according to their initial advantages and pursued economic growth in their hinterland. The number and scale of the secondary hubs grew rapidly, but the gap between them and major hub ports were also expanded. Port competition continued to develop through a division of functions between various ports, for examples, the hub-and-spoke or hub-and-feeder configuration within main Chinese port clusters, such as the Pearl River Delta and the Yangtze River Delta. In foreign countries, the position of the hub port in each sub region is consolidated, with multiple shipping hubs in the shipping system. Intertwined layers of centrality tend to emerge and articulate with each other, as in the generic model of Robinson (1998) in his seminal paper on hub-feeder networks in Asia. External hub ports such as Singapore and Busan maintained their dominance upon a number of Mainland Chinese ports (Ducruet, Lee, & Ng, 2011).

4.3. Networking stage (2010s–)

Networking is a spatial structure supported by the tangible and virtual network with multi centres and nodes. It is a functionally integrated shipping networks in which new links

develop beyond spatial proximity. There are interdependencies and sustainable development dynamics among multiple hubs, as well as co-opetition with each other, but also within China itself (Song, 2003). Each of them have comparable traffic shares and participate in local networks, while connecting with the global network.

The networking shipping system has the following basic characteristics.

Firstly, it exhibits multi-hub spatial agglomeration. There are a number of hub ports within the region, but without a dominant position in either a size or function. Basically, the spatial organisation is not a hierarchical system, but a more flat and flexible network organisation.

Secondly, the connection of the network develops across space. There is a relatively close spatial relationship between multiple hubs and secondary ports. Spatial linkages are not limited to vertical linkages (i.e. one-way connection from larger ports to smaller ports, ports in different sizes may assume different port functions). Therefore, there is a high dependence on each other. The functional connection of each other creates multi-directional and networking, which differs from the traditional hub-feeder system.

Thirdly, functional differentiation and a division of labour appear among ports. Some ports developed into logistics centres while others increased their container traffic volume (see Figure 3).

Session 5, focuses on the empirical analysis of the characteristics of the port container system in the networking stage.

5. The characteristics of MSR shipping system in networking stage

5.1. Multi-hub spatial agglomeration

In this stage, the Peripheral Port Challenge Mechanism (Hayuth, 1981) began to emerge, the development of a small number of major hub ports is restricted by the limitations of the dock and the increasing cost on the cargo handling and port dues. As a result, its development speed is obviously slowing down. The position of secondary ports situated at the periphery of central hubs are further improved because of their development speed is faster than the latter. The mechanism of competition and cooperation between ports have been fully developed. The shipping system has been improved continuously from a hierarchical structure to network. Ports adjacent to each other form a dual hub port

Figure 3. Evolution of the MSR shipping system, 1980s– (a) Growth stage, (b) Hierarchical stage and (c) Networking stage.

model in the Pearl River Delta and the Yangtze River Delta region (see Cullinane, Teng, & Wang, 2005; Wang & Ducruet, 2012). Physical cargo handling operations are partly transferred from Hong Kong to Shenzhen. Ningbo port changed from a secondary node to a central hub port along the MSR, and the development of the Bohai region leans towards large-scale traffic and improved network connectivity. More and more foreign ports are embedded in the MSR shipping system. The challenge of the peripheral port on central hub port is becoming more and more obvious as well as the gap of the port scale began to narrow.

The Chinese port system has transformed into multiple shipping centres. Based on Table 2, the number of Chinese ports connected with the MSR area remains rather few, namely 10, 15 and 19 ports in 1995, 2005 and 2015, respectively, including 10, 13 and 15 mainland Chinese ports. Based on routes data between ports, construct the O-D matrix and calculate the matrix data using Matlab7.1 software according to graph-theoretical tools, we classify Chinese seaports by using the K-means classification method. Three classification results are obtained: major hub ports, secondary hub ports and general ports. According to Table 2, we counted 3 major hub ports, 4 secondary hub ports and 12 general ports in 2015. Among those ports, all major hub ports have maintained their linkages with the MSR area and enjoyed the largest foreland scope from 1995 to 2015. Secondary hub ports have demonstrated a narrower foreland and general ports only maintain strong ties with Southeast-Asian regions.

From the change of hub port, Hong Kong is the only hub port of China connected to the MSR area in 1995. Hong Kong has a wide range of connectivity and acted as a transit port, it plays significant transshipment and re-export functions (Wang, 1998). As already discussed by Wang and Ng (2011), Pearl River Delta ports are close to Southeast and South Asia, and actively connect the MSR as a reflection of the economic vitality of their hinterlands, and their millenary role as gateways of the ancient MSR in modern times. In 1978, China implemented the open door policy. The Pearl River Delta region is the forerunner of the open door policy in China. It is an important economic centre which plays a leading role and an important strategic position in the national economic development. In addition, the gradual spread of container technology across the world in the 1960s first benefited Hong Kong followed by other Pearl River Delta ports in the late 1970s. This “early mover” advantage became gradually redistributed to other regions such as the Yangtze River ports.

In 2005, the status of Shanghai and Shenzhen ports rose rapidly and became hub ports. They even surpassed Hong Kong in terms of port status. In 2015, Ningbo also became a hub port and Hong Kong stepped out of this category to become a secondary hub port. The decline of Hong Kong’s connectivity suggests that China’s international maritime transportation along the MSR area has changed from indirect relation to direct relation.

At the same time, according to Table 2, the spatial extent of the transportation network shifts from south to north. Southwest seaports such as Beihai and Fangcheng left the MSR shipping network while central Bohai ports increased their connectivity in that system. Initially, main hub was in Hong Kong and the secondary hub port was in Shanghai (1995), both in the south of the Yangtze River Estuary. Beihai and Fangcheng kept shipping links with Haiphong, Singapore and Bangkok in 1995, but such linkages disappeared from 2005 onwards. The north ports, such as Qingdao, Tianjin and

Notes: K-means algorithm uses Euclidean distance as similarity measure to find the optimal classification of an initial clustering centre vector V , which makes the evaluation index J minimum. First, choose k objects as the initial cluster centre from the n data objects, other objects were assigned to the most similar clustering according to the similarity of these objects and cluster centres (distance), and then calculate each new cluster centres (the mean of all objects in the cluster), repeatedly, until the standard measure function converges.

Dalian built more routes with the MSR area after 2005 and their status became more important in MSR networks.

The HHI calculation results show that HHI of domestic ports along the MSR area reduced from 0.573 in 1997 to 0.334 in 2016 (see Table 3), which underlines a process of decentralisation during the study period.

The evolution of concentration indices of overseas ports (Table 3) witnesses two major phases: de-concentration and re-concentration. Such a process suggests that the MSR overseas ports went through a dispersion stage (1997–2005) with the inclusion and development of additional nodes and a centralisation stage (2009–2016). Due to a consolidation dynamic around fewer major nodes or hub ports, the evolution of concentration indices for China and Hong Kong ports as well as China-MSR links experienced a dispersion stage (1997–2013). In 2016, the indices presented the number of ports and links are less than before.

Notably, the connection of the top three ports (Hong Kong, Shanghai and Shenzhen) reached 89.5% in 1995. However, this share (Shenzhen, Shanghai and Ningbo) has been decreased to 60.6% in 2015. The proportion of the top three ports has been declining which shows the characteristics of diversification. One of the reasons of Chinese port decentralisation is policy issues. Ports have become an engine of local economic development. Under the mode of port management localisation, the port investment and construction are the common means to promote regional economic development and improve performance. And open investment to foreign country is based on the catalogue for the guidance of foreign investment of 2002 can make up the short of domestic investment. Guangzhou, Xiamen, Qingdao, Tianjin ports received the foreign investment and the other small ports such as Quanzhou, Lianyungang, Taicang port obtained the investment from COSCO and local government. The second reason is that in the process of port development, the increasing throughput and limited resources of port resulted in short supply of port cargo. Hubport, such as Hong Kong began to show the scale inefficiency and supplies were diverted to the surrounding port. Chinese ports began to appear diversification (Wang, Yeo, & Ng, 2014).

5.2. Connection of the network develops across space

Route is a vector index of direction. The orientation and concentration can reflect the direction of the external connection of a port (Wang, 2012). The distribution of routes in foreign ports provides the connection of the network across space.

As mentioned in Table 2, there are 12 general ports in 2015. Half of them (i.e. Quanzhou, Shantou, Taibei, Taichung, Yingkou, Zhoushan) were subsumed into the MSR firstly. The six

Table 4. The number of general ports' routes in 1995, 2005, 2015.

Port	Year	Oceania	Med	East Africa	Southeast Asia	South Asia	Europe	West Asia	Total
Dalian	1995	0	0	0	3	0	0	0	3
	2005	9	4	0	14	2	53	0	82

ports mainly built routes with the ports in Southeast Asia (see Table 4). Dalian port is located in the North China where it is the greatest distance from MSR. In 1995, it only had 3 routes to connect with the ports in MSR. However, it built 159 routes in 2015, especially with the ports in Europe and Southeast Asia. Tianjin port is the largest artificial port in China in winter, Tianjin port area will face an obstacle due to different sea ice levels. But Tianjin port had established 173 routes which covered all the navigating zones in MSR. Guangzhou port is situated in Pearl River Delta and its condition is worse than Shenzhen port and Hong Kong port. It had no deepwater wharfs before Nansha port area launched in 2004. It also faced stiff competition with Shenzhen port and Hong Kong port. In 2015, it built 91 routes with MSR. Except the hub ports and secondary hub ports, the general ports have created more and more linkages with the ports in MSR. As the Belt and Road is an important strategy, it is a good opportunity for the small ports to get the support from central government. Thus, the local governments and ports are eager to develop the close relationships with MSR.

In 1997, the MSR mainly consisted in a main corridor concentrating flows between Hong Kong and Singapore (see also Ducruet et al., 2011). The “heart” of the MSR and the rest of the region being connected through secondary linkages. As mentioned above, an expansion and densification of the corridor still with Hong Kong as the major hub but with stronger connexions with Taiwan and North Europe (Benelux) in 2001. This pattern reinforced over time in 2005, but a significant expansion of the MSR towards Shanghai and Northern China is clearly visible from 2009 onwards. In 2016, fewer overseas ports are connected with Hong Kong/China, especially remote ones, but the volume of flows had witnessed rapid growth across the whole MSR (see Figure 4). This confirms China's MSR policy succeeded and resulted in a much heavier activity than in the past. It also implies that major carriers serving this route and region had increasingly rationalised their services, especially with the advent of mega-ships and slow steaming, resulting in a drastic port selection process.

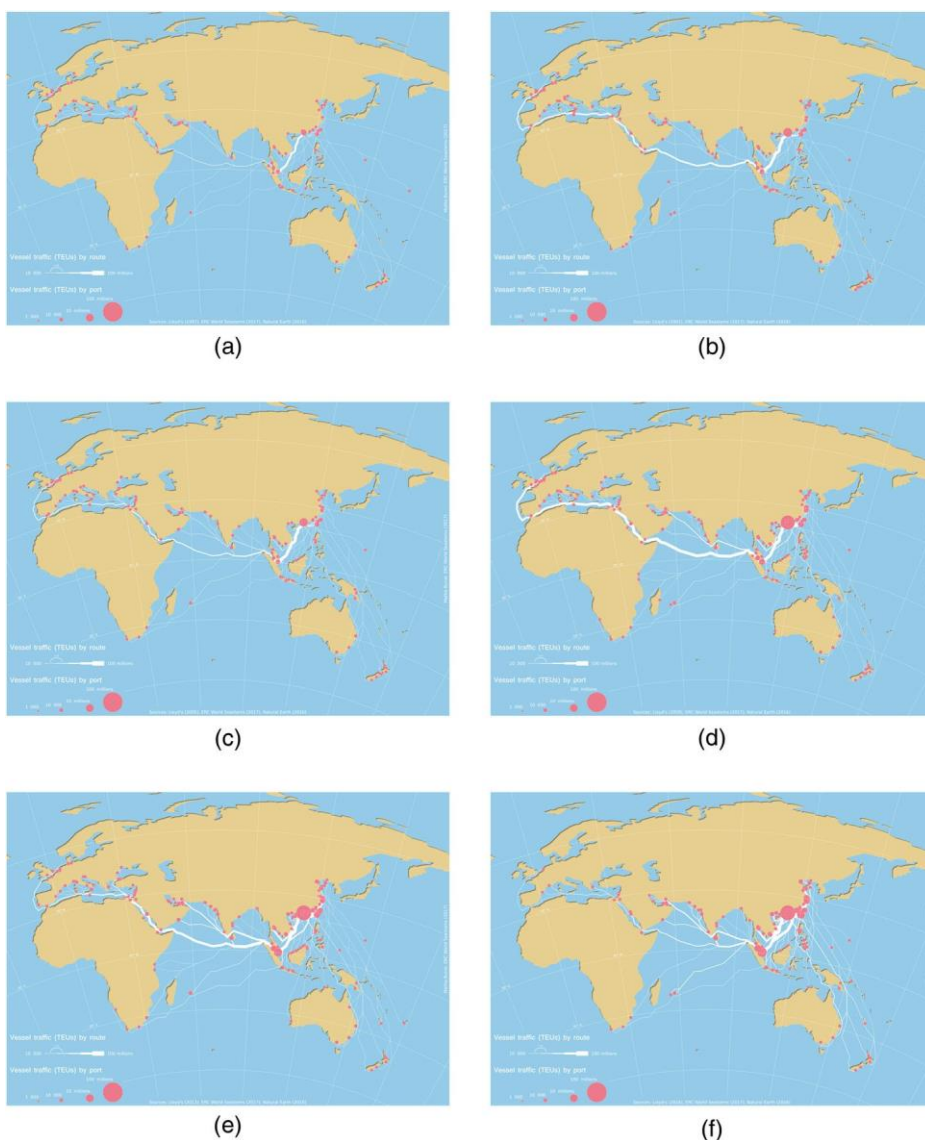

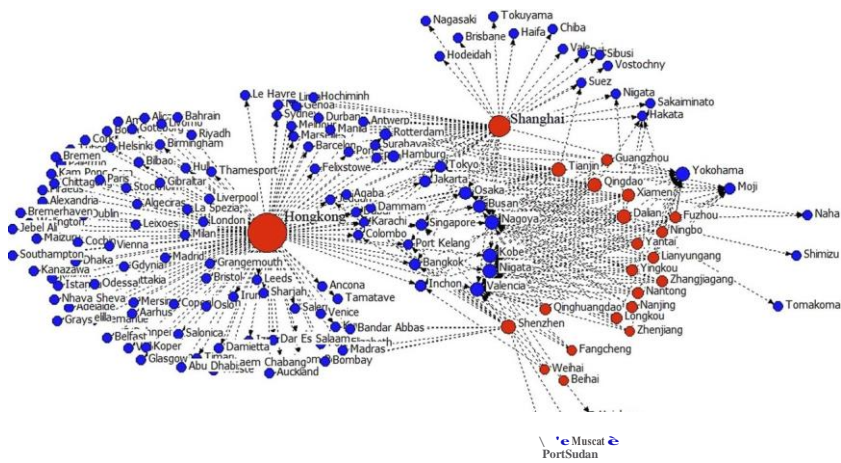

Figure 4. Spatial patterns of maritime transport linkages between China and other countries along the MSR area. (a) 1997, (b) 2001, (c) 2005, (d) 2009, (e) 2013 and (f) 2016. Source: own elaboration based on Lloyd's List Intelligence, 1997–2016.

5.3. Functional differentiation and division of labour appear among ports

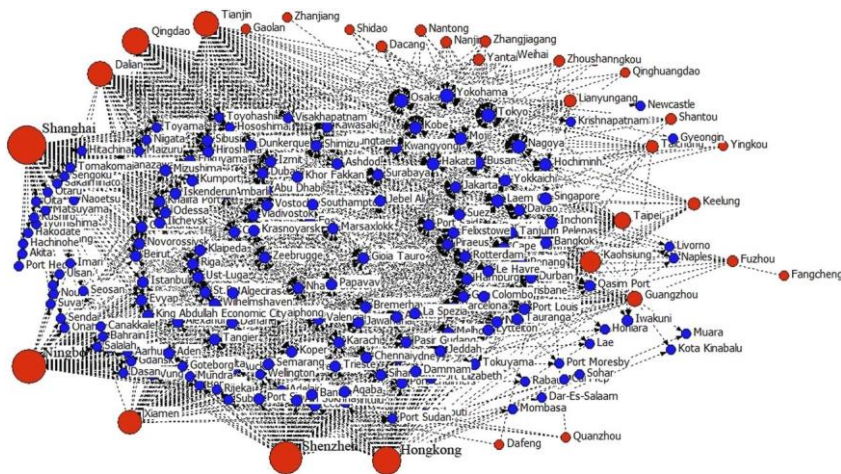

According to the aforementioned classification, China's major hub ports have developed from the single nodal system centred upon Hong Kong to a tripartite system including Shanghai and Shenzhen in 2005, and then to a more polycentric system comprising Shenzhen, Shanghai and Ningbo in 2015. Such an evolution, based on degree centrality, using UCINET software for mapping, is well depicted in [Figure 5](#). Among them, the size of the node indicates the contact area of the port, that is, the importance of the port.

(a)

(c)

Figure 5. A growing polycentricity of the Chinese port system in (a) 1995, (b) 2005 and (c) 2015. Source: China Shipping Weekly, 1995-2015.

The growth rate of Shenzhen port has exceeded the one of Hong Kong from 1995 to 2015, as Shenzhen became China's major hub in 2005. Hong Kong's status declined in container transport as stemming from partial container operators has transferred to Shenzhen. And Hong Kong evolved towards a value chain centre (Wang & Cheng, 2010). Although the respective forelands of Shenzhen and Hong Kong are now overlapping, independent routes were gradually established from Shenzhen overtime. Thanks to open door policy in China, the manufacturing base has shifted from Hong Kong to China. The lower operating cost including labour cost, trucking fee and terminal handling charge has forced logistics companies intend to use Shenzhen as their consolidated logistics centre. The status of Hong Kong is largely determined by the transit function of its international trade goods and the rapid development of mainland ports. This has made Hong Kong cost advantage is further weakened since the twenty-first centuries, resulting in the decline of Hong Kong's position. After entering into WTO, more and more containers are selected from the local ports with more foreign investment diverted to the Pearl River Delta. With foreign equity restrictions lifted, more terminal operators will focus on investments from Hong Kong to mainland ports, for example, Hutchison Whampoa invests intensively on Yantian terminal, Modern Terminals Limited invests heavily on Dachanwan port etc. The growth rate of Shenzhen port far exceeds Hong Kong. More than 60% of the goods directly ship out from the port of Shenzhen without passing through Hong Kong (Cheng & Wang, 2015).

Ningbo's container port developed rapidly and the function of the international container hub port was becoming apparent increasingly (Cullinane, Teng, et al., 2005). Shanghai's connectivity surpassed that of Ningbo's, the latter became closer to the former. However, geographically speaking, the foreland of Ningbo demonstrated much overlapping with the one of Shanghai even for some minor foreign ports. In fact, Ningbo exhibits very few independent and specific connections compared with Shanghai. But as the function of port, Shanghai is eager to develop the high-end shipping service, such as shipping finance, shipping insurance, shipping registration and shipping legal service. The general goal of the construction of Shanghai international shipping centre is that by 2020. It will enter the forefront of the world shipping centres to deploy global shipping resources. Ningbo's port conditions are better than Shanghai. Ningbo intends to ship more containers through sea-rail intermodal transport and 13 dry ports in Zhejiang and Jiangxi provinces. Also, it can tranship oil and ironstone based on its deep water. So, Ningbo and Shanghai ports are able to cooperate with each other to achieve diversified development.

6. Conclusion

From the 1970s–2000s, hub-feeder networks emerged in Asia (Robinson, 1998). Based on complementary and original shipping data sources, this paper analysed China's overseas connectivity along the MSR and its evolution overtime, concluding to the successive emergence of development stages. Among them, networking has been identified in our research as a new stage in such an evolution. Compared with previous studies that touched directly or indirectly the MSR region through maritime network analysis, this paper demonstrated in-depth changes of port system development, such as a peripheral port challenge mechanism, a narrowing gap between ports, hinterland expansion through inland traffic nodes and a closer relationship between foreland and hinterland. This paper

proposes the shipping system development stage of networking in order to provide a theoretical basis for further study on the development of the port system, as claimed by early geographers (Rimmer, 1967). A port system development consists of various components to prepare for maritime logistics and transport hub under MSR. The elements of a port system development contain: new technology, safety, offshore Renminbi hub and liquidity pool, management know-how, the integration of port operators, intermodal transport with an extensive use of railway networks, availability of logistics services, sound ship registration system, deregulation, maritime forum, professional education and training.

Within the overall MSR strategy, China is eager to strengthen the partnership with Central and Eastern European countries so as to maintain regional growth and stability and enlarge the infrastructure networks. Chinese-based carriers like COSCO invested terminal facilities in Piraeus (Greece) not only develops the maritime economies, but also maintains security and peace in the Central and Eastern European regions (The European Union Academic Programme Hong Kong, 2017). In the future, Central and Eastern European regions will be the new emerging container shipping market in the world. The new container shipping routings among China, Central and Eastern European regions will be explored under MSR.

Port system's networking not only represents a new form of spatial organisation, but also carries a new concept of development, emphasising the specialisation and cooperation of every connected port. It is necessary to coordinate their respective interests in order to strengthen their efficient cooperation and connectivity. Hence, an innovative institutional framework is needed to support it, which was designed relatively broadly by the MSR vision. The MSR spans across many countries, which is a port system composed of countries and regions with different interests, facing complex regional coordination and governance issues.

Network shipping systems will be dispersed various functions of the shipping hub and secondary hub port. Also, it keeps spatial contact through the network which provides equal development opportunities for each centre. The co-competition avoids high cooperation management cost between the governments and blind development with a lack of coordination.
