Foreign Demand, Developing Country Exports, and CO₂ Emissions: Firm-Level Evidence from India

Geoffrey Barrows* and H el ene Ollivier†

June 3, 2020

Abstract

Over the past few decades, wealthy countries have relied increasingly on imports from developing countries, prompting concerns regarding the environmental impacts of trade. Some argue that increased exports from developing countries increase global emissions, as environmental regulation in the developing world tends to be relatively weak. But increased exports need not imply increased emissions if domestic sales are jointly determined with export sales or if emission intensity adjusts endogenously to foreign demand. In this paper, we estimate how production and emissions of manufacturing firms in a developing country respond to foreign demand shocks in trading partner markets. Using a panel of large Indian manufacturers and an instrumental variable strategy, we find that foreign demand growth leads to higher growth rates for exports, domestic sales, production, and CO₂ emissions, and to stronger reductions in emission intensity, both at the firm level and at the firm-product level. This represents the first empirical evidence of technological upgradings at the product level net of price effects. In terms of magnitudes, counterfactual computations reveal that the emission intensity reductions mitigate about half of the scale effect (from exports and domestic sales growth) on average.

1 Introduction

Economists, policy-makers, and the general public have been concerned about the environmental consequences of globalization for decades. Central to the debate is the fear that free trade encourages production to shift towards developing countries, where environmental regulation is weak and production less efficient (Antweiler et al., 2001; Frankel & Rose, 2005; Copeland & Taylor, 2004; Levinson, 2009). The rise in exports from developing countries in the recent years makes this fear more salient,¹ especially in a context where international negotiations on climate change have stalled and where governments have been slow to regulate Greenhouse Gas (GHG) emissions.² But recent studies suggest that changes in international conditions also trigger endogenous response at the firm level beyond export sales growth (Forslid et al., 2018; Cui et al., 2015; Cherniwchan, 2017; Gutiérrez & Teshima, 2018; Shapiro & Walker, 2018; Barrows & Ollivier, 2018), which implies that even if globalization increases the demand for exports from the developing world, the impact on emissions is not clear. While there is a large theoretical literature on the impact of free trade on aggregate emissions, there is little empirical evidence of its impact on emissions of individual firms, especially in the developing world.

Three mechanisms in particular suggest that the impact of foreign demand on emissions is theoretically ambiguous. First, using a fixed cost model a la Bustos (2011), several papers argue that any positive shock to demand encourages technological adoption, which could lower firm-level emission intensity (Forslid et al., 2018; Cui et al., 2015; Cherniwchan, 2017; Gutiérrez & Teshima, 2018). The potential for technological upgrading is perhaps strongest specifically in the developing world, where firms operate on average far from the global technological frontier. Second, increased foreign demand may also incentivize multi-product firms to adjust their product mix towards lower-marginal-cost products (Mayer et al., 2014, 2016), which could lower firm emission intensity if these products also have lower emission intensity within firms (Barrows & Ollivier, 2018). Finally, the overall scale of output at the firm level may increase less (more) than the absolute growth in exports if export and domestic sales are substitutes (complements) (Berman et al., 2015). Together, these three mechanisms imply that firm-level emissions need not scale 1-for-1 with firm-level exports, and need not increase at all.

¹See Figure A.3 for the evolution of developing-world export share in total world exports over time.

²Regional regulatory markets have been established in many places in the world, mostly in developed countries, including the EU, California, the US East coast, South Korea, Australia, New Zealand, British Columbia, and Tokyo, among others; but even for these programs, the cost of carbon remains very low, thereby limiting the extent of GHG emission reductions.

In this paper, we provide the first estimates of how changes in foreign markets conditions impacts the CO₂ emissions of individual firms in the developing world. Our analysis focuses on a particular country – India – which offers two key benefits as an empirical context. First, an unusually detailed reporting requirement allows us to track output and energy inputs both denominated in physical units over time at the firm and firm-product levels. The specificity of the data owes to a 1988 amendment to the Indian Companies Act which requires firms to report energy use both by energy source and *by product line* each year. Following recent work, we compute CO₂ emissions by multiplying these self-reported energy usage statistics by CO₂ content emission factors of different energy types and summing over energy types (Martin, 2012; Marin & Vona, 2019; Forslid et al., 2018; Barrows & Ollivier, 2018). With these data, we can estimate the elasticity of firm-level CO₂ emissions to foreign demand, and breakdown the total impact into contributions from scale (both foreign and domestic sales) and technique.³ Secondly, India is a major emitter of CO₂ emissions, and the fastest growing emitter since 1980 of any large country. Hence, identifying the role of trade in India’s emissions growth is important for forecasting global CO₂ emissions and potentially designing effective policy.

To separate the causal impact of foreign demand growth from unobservable determinants of production and emissions of individual Indian firms, we follow recent work in international trade that constructs firm-specific demand shocks from aggregate trade statistics (Hummels et al., 2014; Mayer et al., 2016; Aghion et al., 2019). In particular, we measure product-specific foreign import demand as the weighted sum of aggregate product-specific import demand in India’s destination markets – excluding the contribution from India herself. We then relate these aggregate measures to individual firms based on the set of products offered by the firm. By leaving out India’s own contribution to foreign market import demand, we attempt to purge the demand measures of concurrent determinants of Indian production and emissions. However, global trends in product-specific productivity could also mechanically drive up foreign demand and Indian exports at the same time. Additionally, contemporaneous shares of Indian exports to specific destinations could respond endogenously to unobserved shocks to production. To address these possibilities, we instrument current-year-weighted foreign demand shocks with base-year-weighted foreign demand shocks. We also test formally for differential pre-shock trends for each outcome

³At the firm-level, the technique effect could include both across-product shifts and within-product over time adjustments. We will refer to the latter as “technology”, though changes in managerial practices, fuel source, or quality of inputs could also contribute to a change in emission intensity within a product (Cherniwchan, 2017; Gutiérrez & Teshima, 2018).

variable, as in Aghion et al. (2019).

With a panel of 7,817 Indian exporters for the period 1995-2011, we show that positive foreign demand growth increases firm-level year-over-year growth rates of export sales, domestic sales, unit values, physical production, and CO₂ emissions. Impacts on all outcome variables are statistically significant at least at the 5% level, except for CO₂ emissions, for which impacts are only marginally significant. We thus identify a strong scale effect from positive trade shocks. This scale effect results from an increase in both exports and domestic sales, which suggests that exports and domestic sales are complementary in the Indian context, as in Berman et al. (2015). We also find that firm-level emission intensity – evaluated as CO₂ emissions either per rupee (in value) or per unit of physical output (in quantity) – declines with foreign demand shocks. This finding confirms that firms endogenously adjust technique to trade (be it from product mix or technology). In all specifications, we reject differential pre-shock trends at conventional levels, suggesting that differential product-specific trends do not drive the results. The results are also robust to alternative constructions of foreign demand shocks, treatment of outliers, and sample specifications. These two findings – a positive scale effect that arises from both exports and domestic sales, and a negative technique effect from trade shocks – indicate that it is not sufficient to merely chart the increase in exports from developing countries in order to learn about trade’s impact on the environment.

At the product level, with a panel of 1,292 firm-products, we also find that sales, production and emissions all increase with positive foreign demand shocks, whereas emission intensities in both value and quantity decrease. All estimates are statistically significant at least at the 5% level. With product-mix held constant by construction, these reductions in emission intensity observed at the firm-product level could only come from technological change. This finding thus validates the technology channel posited in Forslid et al. (2018); Cui et al. (2015); Cherniwchan (2017); Gutiérrez & Teshima (2018). Indeed, exporting firms endogenously adjust their technology to positive trade shocks and lower their CO₂ emissions per unit of output for each product. As with the firm level, results are robust to alternative constructions of foreign demand shocks, treatment of outliers, and sample specifications. Long difference estimates yield similar qualitative results. Heterogeneity analysis indicates that emission intensity reductions are driven by below-median-sales firms, but there appear to be no major difference between clean vs dirty firms or clean vs dirty sectors.

To interpret these results, we decompose trade’s impacts on CO₂ emissions growth into

scale and technique effects using counterfactual computations over the period 1998-2011. We estimate that foreign demand growth raised CO₂ annual growth rates 1.8 percentage points via the scale effect and reduced these growth rates by 0.74 percentage points via technique effect on average at the firm-level. Measured against an observed average growth rate of 3.6%, these channels amount to 50% and -21% of the observed growth rates, respectively. Thus, the technique effect mitigates roughly half the scale effect. Overall, foreign demand shocks over the period increased CO₂ emissions growth rates by 1.1 percentage points annually. Somewhat surprisingly, we find that the domestic sales effect is on average roughly the same magnitude as the technique effect (measured in value). With these two channels offsetting each other, we find that emissions in fact scale almost 1-for-1 with firm-level exports on average. Yet, this is not true year by year, and we have no reason to believe the result generalizes.

At the product level, with output denominated in quantity, we estimate that foreign demand growth raised CO₂ growth rates via the scale effect by 0.61 percentage points and reduced them via technique effect by 0.35 percentage points, for a net increase of 0.26 percentage points. Hence, technological upgradings offset more than half of the scale effect, but trade shocks still raise the average annual growth rate of CO₂ emissions at the product level by about 8%. Since the figures are denominated in quantity, the technique effect nets out price effects. By contrast, equivalent calculations based on output denominated in value overstate the magnitudes of scale and technique effects on average by factors of 2 and 3, respectively.

Our paper mainly contributes to literatures on the impacts of trade on emissions either at the firm level (Martin, 2012; Cherniwchan, 2017; Gutiérrez & Teshima, 2018; Holladay, 2016; Forslid et al., 2018) or at the regional and national levels (Antweiler et al., 2001; Frankel & Rose, 2005; Bombardini & Li, 2020). Most of these papers estimate import competition impacts via trade liberalization, or aggregate effects from trade openness. We instead isolate the export demand side impacts to speak most directly to the question of the contribution of developing countries' trade in global CO₂ emissions. Some of these papers have explicitly considered the impact of exporting on firm-level emissions, but empirical estimates are usually based on cross sections (Batrakova & Davies, 2012; Holladay, 2016; Forslid et al., 2018; Barrows & Ollivier, 2018), which conflate causal impacts with selection effects. By contrast, our paper exploits firm-year and firm-product-year variation over time to identify the response of exporters to foreign demand shocks.

Recent work on emissions from manufacturing also speak to some of the same mecha-

nisms we study. Cherniwchan (2017) finds that firm-level SO_2 and $\text{PM}_{2.5}$ emissions levels from US manufacturing decline following tariff reductions on US goods entering Mexico. This finding would suggest that export demand shocks *lower* emissions levels, at least in the US. By contrast Shapiro & Walker (2018) find that changes in foreign competitiveness (a determinant of foreign demand) had little effect on the evolution of criteria air pollutant emissions from US manufacturing over the 1990s and 2000s. Key differences between our paper and these two studies are that we are able to condition on the export status of the firm, and that we observe output in physical units, so we can abstract from price effects. Additionally, operating environments in India are quite different from those in the US, making extrapolation difficult. Bombardini & Li (2020) examine a setting much closer to ours, studying how regional average export tariff reductions affect SO_2 and $\text{PM}_{2.5}$ concentrations in China. In contrast to Bombardini & Li (2020), we focus on the firm-level mechanisms of response. Finally, in a structural model, Caron & Fally (2020) find that if preferences are non-homothetic, a 1% increase in income everywhere would lead to only a 0.88% increase in global CO_2 emissions. Our work complements this structural approach as we study the consequences of demand growth on production decisions at the micro level.

Our work also relates to the literature on the carbon content of trade (Sato, 2014; Aichele & Felbermayr, 2015). Looking at the Kyoto protocol, Aichele & Felbermayr (2015) estimate that trade flows increased by 5% and embodied carbon emissions by 8% between committed and non-committed trade partners after Kyoto was signed. This literature computes emissions as the product of industry-specific carbon intensities in different countries and trade volumes and then estimates responses to environmental policy. A limitation of this approach is that it computes intensity in value and ignores impacts on domestic production, as well as the endogenous response of firm emission intensity to trade shocks. By examining firm-level production data, we can test whether these responses matter for measuring carbon emissions.

Finally, in studying the underlying mechanisms of emission intensity reductions, we relate to the large literature on the determinants of firm-level productivity. This literature mostly estimates the responsiveness of innovation or Hicks-neutral total factor productivity measures to various changes in trade, competitiveness and market conditions (Bernard et al., 2011; Lileeva & Treffer, 2010; Bustos, 2011; Bloom et al., 2016; De Loecker et al., 2016; Mayer et al., 2014, 2016). The literature hypothesizes that both technology adoption and product mix contribute to firm-level changes in productivity. Our estimates of emission intensity at the firm-product level represent the only product-level estimates of

efficiency that we are aware of in the literature, and allow us to provide a direct test of the technological channel.

2 Background and Data

In this section, we present the empirical context, the firm-level production data, and the international trade data from which we compute demand shocks.

2.1 Background

In 2016, India was the third largest emitter of CO₂ emissions (7% of world emissions), behind China (29% of world emissions) and the US (14% of world emissions). Over the period since 1980, India was also the fastest growing emitter of CO₂ among large emitters (initial share greater than 1% of world emissions), with an increase of 689% in total.⁴ A large part of this growth was due to rapid expansion in manufacturing output. Following trade liberalization and other market reforms in the early 1990s, real output from manufacturing grew 313% between 1995 and 2011 (see Goldberg et al. 2010a for a discussion of these reforms). Throughout most of the period, CO₂ emissions were completely unregulated in India. State governments made some efforts to regulate criteria air pollutants like PM_{2.5} and NO_x, though regulation appears to have had limited effect (Greenstone & Hanna, 2014).⁵

Over the same period, exports from India also grew substantially. Between 1995 and 2011, real value of exports grew 658%. Exports to the US grew by a factor of 5, with similar increases in Belgium-Luxembourg, South Korea, Hong Kong, and Singapore. Among destinations accounting for at least 1% of Indian exports in 1995, 7 of the top 10 growth rates occurred in countries considered “high income” by the World Bank. By 2011, the United Arab Emirates accounted for the largest share of Indian exports (12.0%), with the US (11.9%), China (6.6%), Singapore (5.4%) and Hong Kong (3.7%) rounding out the top 5 destination markets. With this huge growth in both CO₂ emissions and exports, the case of India represents a good opportunity to study the environmental consequences of the rise of exports from developing countries.

⁴Data come from the International Energy Agency.

⁵More recently, in 2010, the government introduced a nationwide carbon tax of 50 rupees per tonne on coal, which has since increased to 450 rupees per tonne; though with our period of analysis ending in 2011, the tax is unlikely to have influenced the firms in our sample. We nevertheless include firm specific energy prices as controls in our regressions, thus potentially capturing local regulation effects.

2.2 Manufacturing Data

To study production and emissions at the firm and firm-product level, we rely on a dataset of large Indian manufacturers compiled by the Center for Monitoring the Indian Economy (CMIE). This dataset, which CMIE calls Prowess, is based on annual reports filed publicly by Indian companies, which CMIE collects and digitizes. Registered Indian firms are required to issue these reports annually as part of the Indian Companies Act of 1956. Not all firms file reports every year and not all reports are readily available, but the sample in fact covers a very high share of output from the formal sector (around 80%) starting around the mid 1990s (De Loecker et al., 2016; Goldberg et al., 2010b).

In the annual reports, firms give detailed accounts of both inputs and outputs. On the output side, firms report both value and quantity of sales and production by product line along with units of production.⁶ From these statistics, we can compute unit values. Firms also report the share of revenue earned from exports. We only include firms that report some positive export value at some point over the period in our sample.

On the input side, firms report most standard variables such as labor use, capital and material inputs in value each year. Firms do not directly report environmental emissions; but they report detailed information about energy use.⁷ In particular, firms report annual expenditure and consumption (with units) of different energy sources – coal, electricity, fuel, wood, etc. Additionally, due to an unusual reporting requirement, firms also report energy intensity of production (in units) *by product line*. This reporting requirement was formalized in the 1988 Amendments to the Companies Act, presumably due to government interests in energy security. These annual product-specific energy intensity measures allow us to track technological progress at the product-line level, which, to our knowledge, is not possible in any other dataset.

While for some firms, it might be costly to compute these product-specific energy-use statistics, we learned from telephone interviews that in many cases, different products are

⁶Even though previous work has treated the CMIE product codes as unique identifiers of product offerings within the firm (De Loecker et al., 2016; Goldberg et al., 2010b), we treat the product text description supplied by the firm as the individuating identifier of products (see appendix B for details). For instance, a company named Aarti Steels Ltd. produces four products: “rounds and bars”, “alloy steel castings and steel ingots”, “sponge iron” and “steel billets”. A company named Trident Ltd. produces five products: “cotton yarn”, “towels”, “paper”, “processed yarn”, and “sulphuric acid”. A company named Kriti Industries Ltd. produces four products: “refined oil”, “de-oil cake”, “PVC rigid pipes”, and “PVC fittings”. Another company named Dalmia Bharat Sugar and Industries Ltd. produces four products: “sugar”, “cement”, “deadburnt magnesite”, and “bricks”.

⁷Since the location of production is not reported in Prowess, it is impossible to match production to ambient pollution levels.

produced in different “wings” of an establishment and that firms can fairly easily install “sub-meters” to record electricity use by wings. Also, different product lines often utilize different machines or boilers with specific (known) energy input requirements. Finally, firms also reported using resource planning softwares (for example, the Enterprise Resource Planning tool from the firm SAP) to record input use for each product line.⁸ Still, given that the product-specific energy data is self reported and that compliance with the reporting regulation is not costless, measurement error is a potential concern. To address this concern, we test and reject likely sources of misreporting (See Appendix B for further details).⁹

To compute CO₂ emissions, we follow previous work in multiplying energy consumption by source-specific CO₂ emissions factors (Martin, 2012; Marin & Vona, 2019; Forslid et al., 2018; Barrows & Ollivier, 2018). The underlying assumption behind this strategy is that a given source of energy (eg, coal, fuel, wood) has a fixed carbon content, and that burning the energy source releases that carbon content regardless of the technology used to burn it. This assumption seems reasonable for the case of CO₂ in India, where end-of-pipe carbon capture technology is not widely used. By contrast, one would not want to make the same assumption with respect to criteria pollutants such as NO₂ or PM_{2.5}, for example, for which the emission content can vary significantly with the technology used.

With sales denominated in both value and quantity, we compute emission intensity as kilotonne (kt) of CO₂ per rupees of sales and per physical unit of output. There are advantages and disadvantages to both measures. When measuring emission intensity in quantity, we must restrict units to be common across products and over time to make comparisons, which reduces statistical power. However, this measure is free of price effects, which could be quite important. Previous research suggests that firms set higher prices in richer, larger and more distant destination markets (Manova & Zhang, 2012; Johnson, 2012) or upgrade quality to reach foreign markets (Fan et al., 2015), leading to a positive price effect. By contrast, when emission intensity is computed per rupee of sales, no extra restriction needs to be made for purposes of comparison; but, with the denominator expressed in value, changes in emission intensity will partially reflect endogenous price

⁸The software developed by SAP allows firms to follow their sales and distribution, their materials management, their production planning, as well as their human capital management. (<https://www.sap.com/india/>)

⁹We hypothesize that misreporting could take three forms. First, seeking to minimize the cost of reporting, firms could report pure noise for product-specific energy intensity. Second, firms could use a simple rule of thumb like attributing energy consumption in proportion to sales or production. Third, firms could pick some value for energy intensity (either accurate or not) and report the same value every year. As reported in Appendix B.4, we test and reject all three types of misreporting.

changes. This price effect does not have any environmental meaning: a higher quality/price T-shirt with the same unit CO₂ requirements neither increases nor decreases environmental impact relative to a lower-quality version.

With the two different energy reports, we construct two different datasets. First, we construct firm-level CO₂ emissions by multiplying quantities of individual energy sources by CO₂ emissions factors from the US EPA and then summing over energy sources. By summing outputs over product line and merging, we then compute firm-level output, emissions, and emission intensity. We refer to this first dataset as the “firm-level” dataset because it is based on firm-level energy reports. Second, we compute product-level emission intensity by multiplying product-level energy intensity by the same CO₂ emissions factors and summing over energy types. We then merge these emission intensities to the product level output information. We refer to this second dataset as the “product-level” dataset.

We report descriptive statistics for both datasets in Table 1 by industry. Industry classifications are based on the CMIE product classification codes, which map closely to the more broadly used National Industrial Codes, at the aggregate level at least. The entire Prowess dataset spans the years 1989 - 2017, but our aggregate trade statistics only covers the years 1995 - 2011, so we only include this period in the analysis.¹⁰ After merging input and output variables, we have 7,817 exporting firms in the firm-level dataset. Coverage is fairly broad across the entire manufacturing sector. The average firm in the firm-level dataset generates 1.31 billion rupees in sales per year, or about 17 millions USD. The average firm also earns 26% of revenue from exports and produces just under 5 different products per year. In the product-specific dataset we have fewer firms overall – 1,292 exporters in total. The firms count is smaller in the product-specific dataset for two reasons. First, not all firms report product-specific energy intensities. Second, merging product-line inputs to product-line outputs is a complicated process and is not possible in all cases, even when both data reports existed (see the Appendix for details). In the product-level dataset, the average firm generates 1.05 billion rupees in sales on 2.42 products per year.

Table 2 presents descriptive statistics in levels (columns 1 to 5) and in growth rates (columns 6 to 10) for both datasets. Columns (1)-(2) and (6)-(7) report means and standard deviations of variables. Growth rates between year $t - 1$ and year t for variable Y are computed as follows: $\Delta Y_{t,t-1} = (Y_t - Y_{t-1}) / [\frac{1}{2}(Y_t + Y_{t-1})]$. Columns (5) and (8) report the number of observations for each variable, columns (4) and (9) the number of firm-

¹⁰We ran some diagnostic tests using the early years (1989 - 1994) to test for pre-period trends in outcome variables, but very few firms have reports going back that far, so the estimation was underpowered.

Table 1: Firms by Industry

Industry	Firm-Level Data				Product-Level Data		
	# Firms	Average Values			# Firms	Average Values	
		Sales	Export	# Products		Sales	#
			Share				Products
(1)	(2)	(3)	(4)	(5)	(6)	(7)	
Food, Bev. & Tob.	562	1.556	0.276	5.590	99	1.215	2.868
Textiles	1398	0.959	0.331	3.782	413	0.864	1.727

Base Metals	1123	1.470	0.218	4.372	219	1.236	1.740
Machinery	1418	1.177	0.234	5.918	56	0.743	1.383
Transport Equipment	513	1.684	0.222	5.207	34	1.148	1.686
Total	7817	1.312	0.261	4.995	1292	1.054	2.426

Notes: Table reports total number of firms by industry along with industry average values per year in firm-level dataset (columns 1-4) and product-level dataset (5-7). Data covers the period 1995-2011. Firms are assigned to an industry based on the product that accounts for the greatest aggregate sales over the entire period. Sales are reported in billions of current year rupees.

products, and columns (5) and (10) the number of firms. Panel A describes the firm-level dataset in which we observe that the number of observations is the highest for sales and output variables, whereas it is reduced by half for emissions and emission intensity measures for lack of reporting. Since units of quantity vary across products and firms, we cannot interpret the numbers for production and unit value. In the regressions, we will condition on common units within the firm over time. We find that Indian firms experience on average a 8.7% growth in sales per year, while reducing their emission intensity in value (in quantity) by 2.3% (resp. by 1.6%). Panel B describes the firm-product dataset, which contains even fewer observations but with a relatively stable number of them across variables. We find that, within a firm, a product experiences on average a 5.5% growth in sales, while emission intensity per product declines by 2.6% when computed in value and by 0.6% when computed in quantity.

Table 2: Descriptive Statistics

	Levels					Growth Rates

Notes: Table reports firm-level (A) or product-level (B) descriptive statistics in levels (columns 1-5) and growth rates (columns 6-10). Data covers 1995-2011. F-P stands for firm-products. For each variable, top/bottom 1% of firm-year or firm-product-year values have been removed. For production, unit values, and emission intensity in quantity, growth rates are only computed if output is denominated in the same units across products within the firm-year and across consecutive firm-years. Currency values are billions of current year rupees.

2.3 Trade Data and Identification of Export Shocks

Our goal is to relate exports, CO₂ emissions, production, and emission intensity to exogenous foreign demand shocks in trading partner markets. To do so, we employ techniques from the trade literature that suggest plausibly exogenous measures of foreign demand changes year to year. Broadly, the strategy is to construct weighted average foreign import demand in countries that India tends to sell to, product by product, leaving India’s own exports to the destinations out of the measure of import demand, and then instrumenting these measures with base-year weighted average shocks. We follow Mayer et al. (2016) and Aghion et al. (2019) in building our foreign demand shocks and in interpreting changes in these measures as shocks to the demand for exports from individual producers.

To construct export demand shocks, consider an Indian exporter producing a product j at date t . Using aggregate trade data, we observe over the entire period that Indian products j are sold in destinations $d \in \Omega_d$, where Ω_d is the set of all destinations India exports j to. Let X_{djt} denote the aggregate import flow in product j into destination d from all countries except India at time t . Thus, X_{djt} reflects the size of the (j, d) export market at time t . The intuition is that subsequent changes in destination d ’s imports of product j from the world (except from India) serve as a good proxy for the change in export demand faced by Indian firms operating in market j . By leaving India’s own exports out of X_{djt} , we seek to purge the equilibrium values X_{djt} of supply side effects that might jointly affect Indian exports and production. We then compute the change in product-level demand based on Davis-Haltiwanger growth rate and sum across destinations d weighted by the current-year relative importance of destination d for Indian firms:

$$\Delta FD_{jt,t-1} = \sum_{d \in \Omega_d} s_{djt,t-1} \left(\frac{X_{djt} - X_{djt-1}}{\frac{1}{2}(X_{djt} + X_{djt-1})} \right), \quad (1)$$

where $s_{djt,t-1} \equiv \frac{1}{2} [X_{djt-1}^{\text{from India}} / \sum_{\ell} X_{\ell jt-1}^{\text{from India}} + X_{djt}^{\text{from India}} / \sum_{\ell} X_{\ell jt}^{\text{from India}}]$ is the share of exports that flow to destination d in the total exports of j from India in the combined years $t - 1$ and t , with $\sum_d s_{djt,t-1} = 1$. The Davis-Haltiwanger growth rate operates similarly to a first difference, but preserves observations when the shock switches from 0 to a positive number or vice versa (a notorious feature of international trade statistics), and takes a maximum value of -2 and 2.

The measure $\Delta FD_{jt,t-1}$ reflects the current-year shock (between $t - 1$ and t) to foreign demand faced by Indian producers of j . While the change in X_{djt} can arguably be taken as exogenous, the export shares $s_{djt,t-1}$ are likely determined in part by unobserved shocks

to production in India. To address this endogeneity concern, we compute an instrument for $\Delta FD_{jt,t-1}$ using base-period (t_0) Indian export weights:

$$\Delta Z_{jt,t-1} = \sum_{d \in \Omega_d} s_{dj t_0} \left(\frac{X_{djt} - X_{djt-1}}{\frac{1}{2}(X_{djt} + X_{djt-1})} \right), \quad (2)$$

where $s_{dj t_0} \equiv X_{dj t_0}^{\text{from India}} / \sum_{\ell} X_{\ell j t_0}^{\text{from India}}$. We use for base-year weights $s_{dj t_0}$ the average values over 1995–1997 for the beginning of the sample (1995–2004), and the averages over 2002–2004 for the end of the sample (2005–2011). The reason to change the weights for the latter period is that trade patterns changed a lot over the period, and so export shares from 1995–1997 may not be very informative for Indian firms later in the sample. We take the split-sample weighting scheme as our baseline, though results are not substantially different if we leave weights fixed at 1995–1997 values throughout.

To construct firm-level foreign demand shocks, we weight product-level shocks by the relative importance of each product in the firm’s total sales, and aggregate. For the endogenous foreign demand shocks, we compute for firm i ,

$$\Delta FD_{it,t-1} = \sum_{j \in \Omega_{it,t-1}} r_{ijt,t-1} \Delta FD_{jt,t-1}, \quad (3)$$

where $r_{ijt,t-1} \equiv \frac{1}{2}[V_{ijt-1}/(\sum_{h \in \Omega_{it-1}} V_{iht-1}) + V_{ijt}/(\sum_{h \in \Omega_{it}} V_{iht})]$ is the sales share of product j in firm i ’s total sales in the combined years t and $t-1$, and $\Omega_{it,t-1}$ is the set of products offered by firm i in years t and $t-1$. For the base-year weighted foreign demand instruments, we compute:

$$\Delta Z_{it,t-1} = \sum_{j \in \Omega_{it_0}} r_{ijt_0} \Delta Z_{jt,t-1} \quad (4)$$

where $\Delta Z_{jt,t-1}$ is computed in (2), and $r_{ijt_0} \equiv V_{ijt_0} / \sum_{h \in \Omega_{it_0}} V_{iht_0}$ the sales share of product j in firm i ’s total sales in base year t_0 , and Ω_{it_0} is the set of products produced in base year t_0 . In practice, we take the first year of entry of each firm as the base year to define the product weights, and then exclude this year from the regressions. This ensures that product sales shares do not respond to future foreign demand shocks.

To compute demand shocks, we take international trade flows from CEPII’s BACI dataset, which reports values of bilateral trade flows at the 6-digit Harmonized System (HS) product classification level from 1995 until 2011. For each product code, we compute

a weighted average foreign demand shock faced by Indian firms, and then merge these shocks to Prowess via the CMIE product classification code. CMIE classifies product names (reported by the firms) according to a 16-digit code of their own design. There are 3,276 CMIE product codes to which we can assign foreign demand values. To exploit differential growth rates in foreign demand at a granular level – across varieties of products within an industry – we construct our own cross-walk between the CMIE product codes and HS revision 1996 (see appendix B.5 for details).¹¹ In a slight abuse of notation, we use j to index either HS product categories or product codes in Prowess. Industry average indices of foreign demand are plotted in Figure A.1 using BACI product codes (Panel A) and Prowess product codes (Panel B). In both panels, we see that foreign demand increased dramatically from the vantage point of Indian firms over the period. The industry that saw the largest increase was nonmetallic minerals, which increased between 4- and 6-fold. This growth was mostly driven by demand for concrete.¹²

Our instruments $\Delta Z_{jt,t-1}$ and $\Delta Z_{it,t-1}$ have been constructed in a similar way to standard shift-share or “Bartik” (Bartik, 1991) instruments. Indeed, the time variation in our shocks only stems from the variation in the world export flows X_{djt} and not in the product-destination weights s_{djt_0} or in the firm-product weights r_{ijt_0} , which are fixed at their value in the pre-period. As in Borusyak et al. (2019), identification in our setting rests on the assumption that shocks are exogenous, and not that exposure shares are exogenous. Given this assumption, as long as there is enough variation in demand shocks across products within industries, we should have enough power to identify effects. We check this condition in Appendix Figure A.2, wherein we plot the cumulative distribution of Davis-Haltiwanger growth rates in foreign demand (left panel) and the residual growth rates after stripping out product code and industry-by-year fixed effects (right panel). The inner quartile of absolute (residualized) current-year weighted foreign demand growth ranges from -.043 (-.062) to .125 (.063), indicating that even controlling for average levels and arbitrary industry trends there is still a substantial amount of variation in year-over-year product-specific growth.

¹¹An alternative mapping relies on the CMIE cross-walk between their 16-digit codes and National Industrial Codes (NIC), which can then be related to the HS codes via the cross-walk from Debroy & Santhanam (1993) (see De Loecker et al. (2016) for an example). However, the cross-walk from Debroy & Santhanam (1993) is fairly aggregated and relies on the version of the NIC from the early 1980s. Hence, the resulting variation would be fairly constant across products within an industry.

¹²Results below are robust to excluding this outlier. See Appendix Figures A.7 and A.10.

3 Empirical Strategy

To identify the impact of foreign demand on firm and firm-product level outcomes, we estimate a standard difference-in-difference model in growth rates, instrumenting current-year weighted trade shocks with base-year weighted trade shocks. The identifying assumption is that once we control for arbitrary industry-by-year trends, variations in instrumented firm-specific demand shock are uncorrelated with firm-specific technological shocks.¹³ The main threat to identification in this setting would be that some product-specific technological trends drive both foreign demand and firm-level output and emissions. To address this concern, we test for correlations of all contemporaneous outcome variables with *future* shocks. If common trends drive up both firm-level output and foreign demand, then we should see comparatively higher firm-level growth for firms that will see larger demand shocks one or two years ahead. Additionally, since technological change may take a few years to materialize, we include several years of lagged demand shocks in the main specification.

Thus, we estimate at the firm level:

$$\Delta Y_{ikt,t-1} = \sum_{\tau=-z'}^z \beta_{\tau} \Delta F D_{it-\tau,t-1-\tau} + \gamma \alpha_k \chi_{t,t-1} + \epsilon_{ikt} \quad (5)$$

where $\Delta Y_{ikt,t-1}$ is an outcome for firm i in industry k measured using the Davis-Haltiwanger growth rate between t and $t - 1$: $\Delta Y_{ikt,t-1} = (Y_{ikt} - Y_{ikt-1}) / [\frac{1}{2}(Y_{ikt} + Y_{ikt-1})]$, and where we instrument each $\Delta F D_{it-\tau,t-1-\tau}$ by $\Delta Z_{it-\tau,t-1-\tau}$. We include an industry indicator α_k interacted with year interval fixed effects $\chi_{t,t-1}$ to capture industry-specific trends, such as labor regulations, income shocks, and general technological progress.¹⁴ Industries are defined as in Table 1. We associate each firm to a single industry based on the product code responsible for the largest share of sales for the firm over the whole period. The specification in first difference (5) eliminates any bias that would arise from a correlation between non-time varying firm characteristics and the *level* of demand shocks. The advantage of this specification lies in the fact that changes in demand shocks $\Delta F D_{it,t-1}$ are substantially less likely to be correlated with firms' observable and unobservable characteristics than levels of foreign demand. As a result, this specification is less susceptible to suffer from

¹³In a specification in 'levels', we would include a firm fixed effect to control for non time-varying characteristics of firms. Yet, in a first difference specification, this is no longer necessary.

¹⁴Unlike in Mayer et al. (2016) and Aghion et al. (2019), our exposure shares s_{djt_0} and r_{ijt_0} sum to one, which implies that we do not need to control for them in our regressions (as explained in Borusyak et al. 2019).

pre-trends than the equivalent estimation done in levels.¹⁵

We next estimate foreign demand impacts directly at the product level using the firm-product dataset. In this case, the identifying assumption is that once we control for any industry-level variation by year, as well as for non time-varying firm-product characteristics, subsequent variations in instrumented product-specific demand shock are uncorrelated with firm-product-specific technological shocks. Considering outcomes at the firm-product level, such as output, emissions, or emission intensity generated by firm i to make product j , we estimate

$$\Delta Y_{ijkt,t-1} = \sum_{\tau=-z'}^z \beta_{\tau} \Delta F D_{jt-\tau,t-1-\tau} + \gamma \alpha_k \chi_{t,t-1} + \epsilon_{ijkt} \quad (6)$$

where $\Delta Y_{ijkt,t-1}$ is the firm-product equivalent to firm-level growth rates $\Delta Y_{ikt,t-1}$, and where we instrument each $\Delta F D_{jt-\tau,t-1-\tau}$ by $\Delta Z_{jt-\tau,t-1-\tau}$. We include an industry indicator α_k interacted with year interval fixed effects $\chi_{t,t-1}$ to capture industry-specific trends for each product category. Note that specification (6) identifies a causal impact from changes in product-specific demand shock $\Delta F D_{jt,t-1}$, not from firm-level demand shock $\Delta F D_{it,t-1}$.

4 Results

In this section, we investigate how foreign demand shocks affects CO₂ emissions and emission intensity of individual Indian manufacturers. We first trace the impacts of these shocks through firm-level export, domestic, and total sales, production, unit values, CO₂ emissions, and finally CO₂ emission intensity. We then explore the equivalent impacts at the firm-product level.

4.1 Firm-Level Response to Foreign Demand Shocks

We first show that our foreign demand shocks impact firms' total sales and production. We estimate equation (5) via GMM, instrumenting $\Delta F D_{it-\tau,t-1-\tau}$ by $\Delta Z_{it-\tau,t-1-\tau}$ for $\tau \in \{-2, 3\}$, and taking the growth rate of total sales, respectively domestic and foreign sales, unit value and total output (in physical units) as our outcome variable $\Delta Y_{ikt,t-1}$. When estimating effects on output in physical units and unit values, we include only firm-year observations for which all products produced by the firm in consecutive years

¹⁵Indeed, we ran the equivalent estimation regression expressed in levels and observed pre-trends for several firm outcomes. We thus focus on the first difference strategy for all our results.

are denominated in the same units. Most physical units are reported in tonnes, so this restriction does not drop many firms in the regression. Since we include 3 years of lagged trade shocks and 2 years of leads, the outcome data span years 1999 - 2009, while trade shocks span 1995 - 2011. We trim the top and bottom 1% of all outcome values and trade shocks, and all regressions control for industry trends. Standard errors are clustered on the 4-digit product code responsible for the largest share of firm sales over the period.¹⁶

We report results for estimated coefficients β_τ (dots) and their confidence intervals (95% as bars) graphically in Figure 1 for $\tau = -2, \dots, 3$. The β_τ coefficients for $\tau > 0$ represent a response of the outcome variable $\Delta Y_{ikt,t-1}$ to a demand shock $\Delta F D_{ikt-\tau,t-1-\tau}$ τ years earlier, whereas coefficients for $\tau < 0$ represent a response to a demand shock $-\tau$ years later. Note that in India the accounting year spans from April 1st of year t to March 31st of year $t + 1$. By contrast, trade data spans from January 1st to December 31st. Thus, the coefficient associated with $\tau = 1$ corresponds to the main contemporaneous effect (including 9 months of synchronous changes) whereas the coefficient associated with $\tau = 0$ corresponds to the early month effect (including 3 months of synchronous changes).

Panel a) of Figure 1 shows a strong contemporaneous and lagged response in total sales to foreign demand shocks. Based on a sample of 20,031 firm-year observations, point estimates imply that a 1 percentage point (p.p.) increase in foreign demand growth (say from 5% to 6%) leads to a 0.27 p.p. increase in firm-level sales in period $\tau = 0$, 0.19 p.p. increase in period $\tau = 1$, and 0.13 p.p. increase in period $\tau = 2$, all statistically significant at the 1% level. Measured against a mean growth rate of 8.7%, this amounts to about an 7% increase in the growth rate. The Kleibergen-Paap rk LM statistic for the estimation is 19.03, which easily surpasses the critical value necessary to reject that the correlation matrix between endogenous and exogenous regressors has less than full rank. The impact of *future* shocks (β_{-1} and β_{-2}) in current growth rates are small and statistically indistinguishable from zero, which is inconsistent with differential pre-shock trends. We also find similar patterns in both the OLS (Figure A.5) and the reduced form (Figure A.4). These results essentially replicate the findings in Mayer et al. (2016) and Aghion et al. (2019) for Indian firms: foreign demand shocks raise firm-level sales.

We next examine to what extent this sales response reflect changes in real production vs price effects. In panel c) of Figure 1, with a sample of 13,249 observations, we esti-

¹⁶The CMIE product code follows a “tree-structure”, so that all products that begin with the same string of digits belong to a common family. For example, all products that begin with the same 4 digits are part of a common group. We cluster on this aggregate product category to allow for correlation in the error term across closely related products.

mate that a 1 percentage point increase in foreign demand growth leads to a 0.11 p.p. increase in real output in period $\tau = 0$ and to a 0.22 p.p. increase in period $\tau = 1$, with only β_1 statistically significant at the 1% level. Measured against a mean growth rate of 6.7%,¹⁷ the impact from $\tau = 1$ amounts to about a 3% increase in the growth rate. The Kleibergen-Paap rk LM statistic for the estimation is 18.12; and, again, small and statistically insignificant estimates of β_{-1} and β_{-2} imply no differential trends prior to demand shocks. Taking unit value as the outcome variable, we find in panel a) a strong and statistically significant impact of contemporaneous ($\tau = 0$) shocks, with small and statistically insignificant estimates for all other τ 's. Hence, part of the sales effect can be explained by higher unit values, though there remains a strong impact on physical production as well.

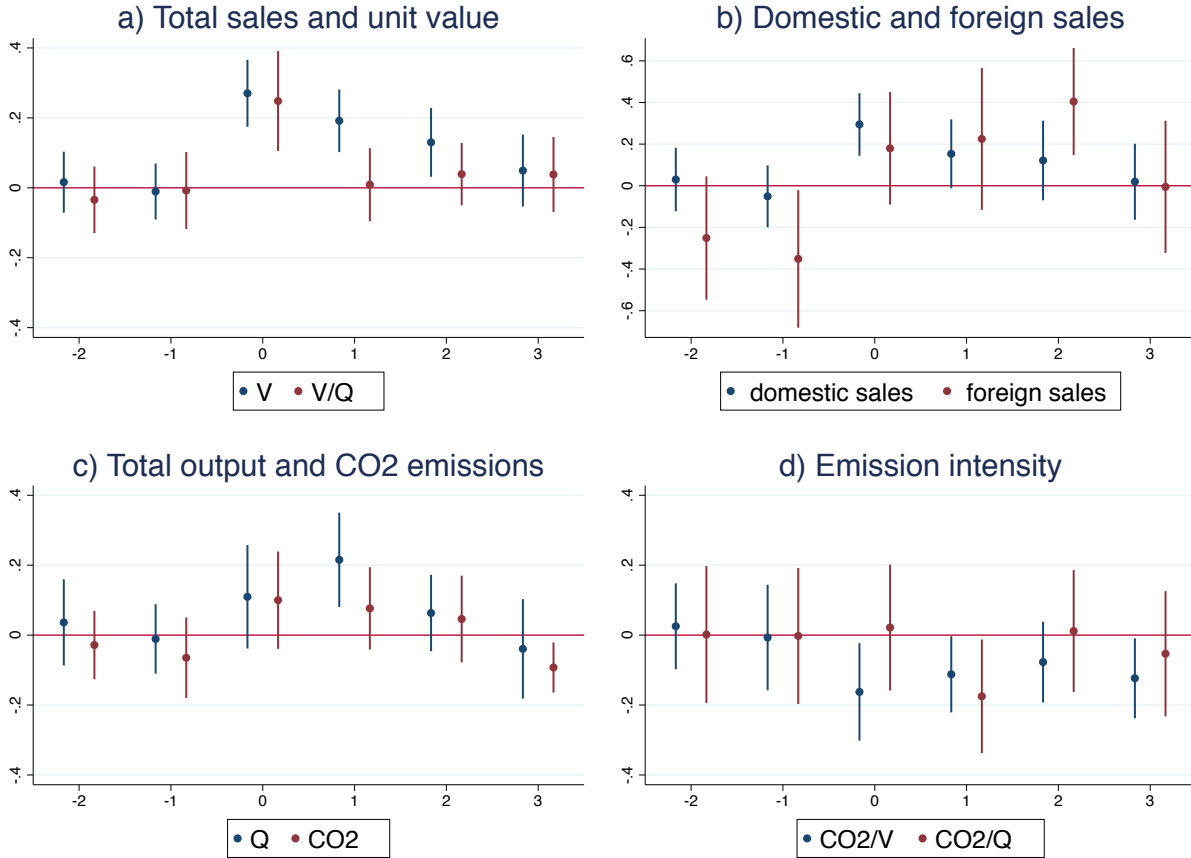

Next, we decompose the total sales effect into foreign vs domestic sales. Most leading models of international trade (such as Mayer et al. (2016); Bernard et al. (2011), among others) feature segmented markets, which imply that conditions in foreign markets do not affect sales in the domestic market. However, some recent empirical work suggests that complementarities may cause foreign and domestic sales to be determined jointly. Berman et al. (2015) hypothesize that increased export sales relaxes liquidity constraints for the firm, which lowers the marginal cost of production overall, thus increasing domestic sales.¹⁸ Alternatively, if firms face short-run credit constraints, then a firm might not be able to increase production year-to-year to meet higher foreign demand. Instead, firms might reallocate sales away from the domestic market. Evidence of credit constraints from Feenstra et al. (2014) would be consistent with such a mechanism. Thus, positive trade shocks could produce either positive or negative effects to domestic sales.

In panel b) of Figure 1, with a sample of 16,358 firm-year observations, we find that positive foreign demand shocks tend to raise export sales. Point estimates imply that a 1 percentage point increase in foreign demand growth leads to a 0.17 p.p. increase in export value in period $\tau = 0$, 0.22 p.p. increase in period $\tau = 1$, and 0.40 p.p. increase in period $\tau = 2$, with only β_2 statistically significant at the 1% level. Measured against a mean growth rate of 8.7%, the impact from $\tau = 2$ amounts to about a 5% increase in the growth rate. The Kleibergen-Paap rk LM statistic for the estimation is 18.96. There appears to be a marginally significant impact from the lead trade shock, which could indicate differential trends in product-specific factors, though we find no such pattern in the reduced form (see

¹⁷The reason why this figure differs from the one quoted in Table 2 is that here it is the average growth rate for observations with constant units across products and between consecutive years.

¹⁸For instance, when foreign demand expands, the increase in exports could allow firms to use their order book as a collateral or as a signal to obtain external financing.

Figure 1: Firm-level results, Instrumental Variables

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO_2 emissions (CO_2), and panel d) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 10.96 (for CO_2/Q) to 19.03 (for V). Number of firm-year observations range from 6,463 (for CO_2/Q) to 20,031 (for V).

Figure A.4). Turning to domestic sales, with a sample of 19,742 observations, we estimate that a 1 p.p. increase in foreign demand growth leads to a 0.30 p.p. increase in period $\tau = 0$ and to a 0.15 p.p. increase in period $\tau = 1$, statistically significant at the 1% and 10% levels, respectively. Measured against a mean growth rate of 9.9%, the estimates imply about a 5% increase in the growth rate. The Kleibergen-Paap rk LM statistic for the estimation is 18.85. Here, impacts from lead shocks are small and statistically insignificant.

The positive domestic sales response is consistent with the liquidity constraint channel

posited by Berman et al. (2015), as well as the empirical evidence from French firms in Berman et al. (2015). The fact that domestic sales tend to respond immediately to foreign demand shocks whereas foreign sales respond a year or two later could be because Indian exporters are not active in foreign markets every year, and hence impacts take a few years to materialize. In any event, the strong domestic sales impact reveals complementarities between domestic and foreign sales, and indicates that the scale effect from domestic sales should be accounted for in the environmental impacts of trade shocks.

Finally, we turn to CO₂ emissions and CO₂ emission intensity at the firm level. Panel c) reports estimates for CO₂ emissions, while panel d) reports impacts on emission intensity in value (CO₂/V) and in quantity (CO₂/Q). When treating CO₂/Q as the dependent variable, we restrict to constant units across products and consecutive years. All the same restrictions and controls apply as in panels a) and b). Responses of CO₂/V to foreign demand will include price impacts, whereas impacts on CO₂/Q reflect real emission savings. Both measures can reflect product-mix effects (across-product shifts) and technological effects (within product-line effects over time), such as fuel switching or technological upgrades.

In panel c), with a sample of 10,116 observations, we find that CO₂ emissions increase with positive foreign demand shocks, as we found for production, but compared to total production, the impacts are muted and only marginally significant (p-values .15 and .20 for $\tau = 0$ and 1, respectively). The point estimates imply that a 1 percentage point increase in foreign demand growth leads to a 0.10 percentage point increase in period $\tau = 0$, and 0.08 percentage point increase in period $\tau = 1$. The Kleibergen-Paap rk LM statistic for the estimation is 12.06. The fact that both sales and production increase more than emissions suggests that emission intensity in both value and quantity must fall with foreign demand. In fact, panel d) confirms this result: with samples of 10,120 and 6,463, respectively, we estimate that a 1 percentage point increase in foreign demand growth leads to 0.16 and 0.11 p.p. lower growth in periods $\tau = 0$ and $\tau = 1$ for CO₂/V, and to 0.18 p.p. lower growth in period $\tau = 1$ for CO₂/Q, all statistically significant at the 5% level. The Kleibergen-Paap rk LM statistic are 11.99 and 10.96. Evaluated at mean growth rates, these figures imply approximately 12% and 49% reductions in growth rates for firm emission intensity in value and in quantity, respectively, due to a 1 p.p. increase in foreign demand growth.

The latter result indicates that firms' environmental performance improves with positive foreign demand shocks, though not enough on average to counteract a positive scale effect. The novelty of our results consists in demonstrating that firm emission intensity reductions

caused by trade shocks translate into reductions in emissions per *physical* unit of output, and that, even though price effects do exist, they cannot explain all emission intensity reductions.¹⁹

For all firm-level results, we present robustness checks in the Appendix in which we alternatively suppress the top and bottom 2% of firm-year outcome values and demand shocks (Fig. A.6), and we exclude nonmetallic minerals (Fig. A.7). The first exercise is a fairly common check. In the second case, we test for robustness because nonmetallic minerals exhibited much higher growth over the period than the other industries. We find that results are qualitatively the same, though we note that the 95% confidence interval for the emission intensity in quantity result includes zero in the case where we exclude top and bottom 2% outliers.

The emission intensity reductions measured per unit of physical output observed in panel d) could owe to the product-mix effect hypothesized in Barrows & Ollivier (2018), Cherniwchan (2017) and Cherniwchan et al. (2017), and/or to the technology channel posited by Forslid et al. (2018); Cui et al. (2015); Cherniwchan (2017); Gutiérrez & Teshima (2018); Shapiro & Walker (2018). Presumably, the technology channel would deliver greater benefit to the environment, as technological investment has an element of irreversibility, while product mix can be adjusted year to year.²⁰ In order to isolate the technological channel, we can estimate impacts at the firm-product level using our detailed dataset, holding product-mix and price channels fixed.

4.2 Firm-Product-Level Response to Foreign Demand Shocks

At the firm-product level, we estimate equation (6) by GMM, instrumenting $\Delta FD_{jt-\tau,t-1-\tau}$ by $\Delta Z_{jt-\tau,t-1-\tau}$ for $\tau \in \{-2, 3\}$, and taking the growth rate of total sales, unit value, and total output (in physical units) as our outcome variable. As before, we trim the top and bottom 1% of trade shocks and outcome values, we control for industry trends, and we cluster standard errors on the 4-digit Prowess code of the product. At the firm-product

¹⁹Previous research has tied various measures of trade to emission intensity in value (CO₂/V) at the firm level. For example Cherniwchan (2017) estimates that NAFTA-induced reductions in tariffs on US goods entering Mexico resulted in lower SO₂ and PM_{2.5} emission intensity in value at US plants, Cui et al. (2015) find that exporters have lower emission intensity in value than non-exporters, also in the US, and Gutiérrez & Teshima (2018) find that increased import competition in Mexico leads to reductions in plant-level energy intensity in value. But we are not aware of any other research that connects trade measures to emission intensity *in quantity*.

²⁰Again, “technology” is construed broadly to encompass any reduction in emission intensity in quantity at the product-line level.

level, we also cluster standard errors to allow for arbitrary correlations in the error terms across products within the firm and over time.

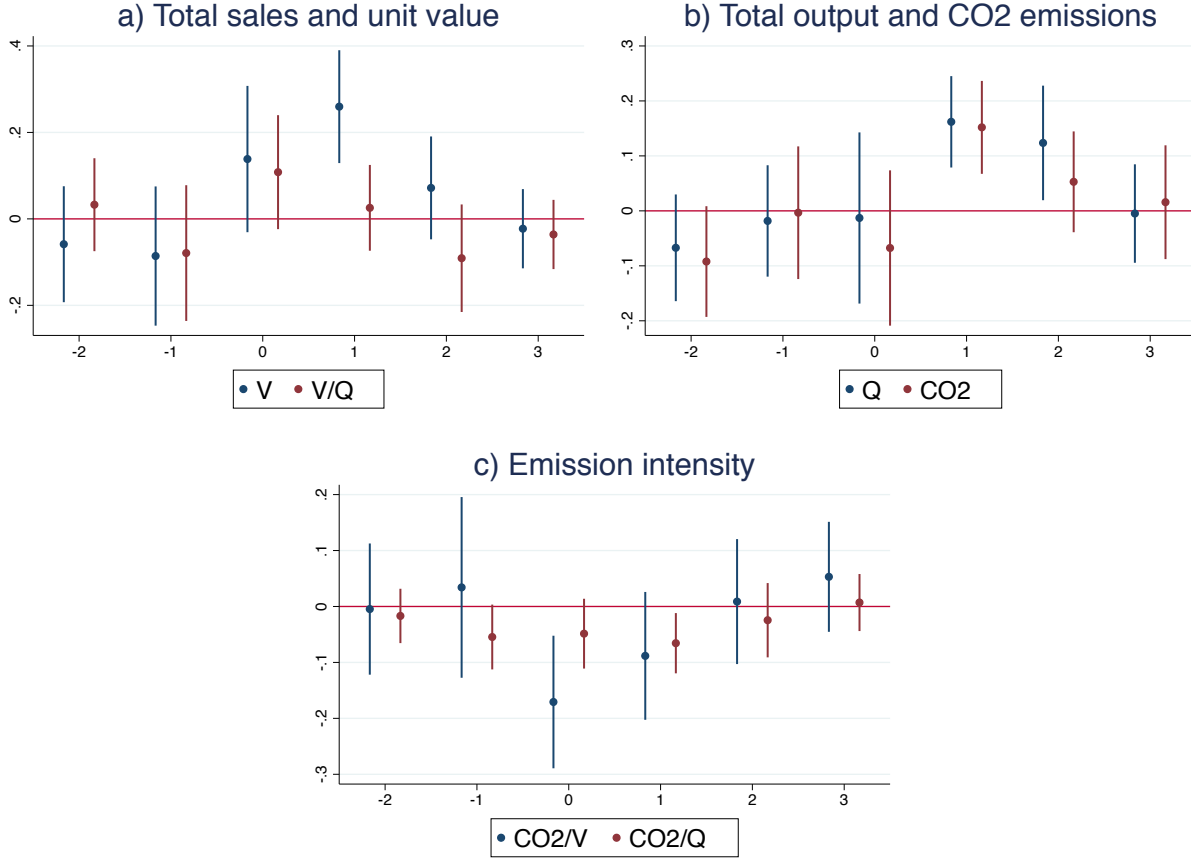

Figure 2 presents results graphically. Panels a) and b) show statistically significant and economically meaningful responses of firm-product sales (V) and output (Q) to foreign demand shocks. With a sample of 7,835 firm-product-year observations across 1,501 firm-products, we find that a 1 percentage point (p.p.) increase in foreign demand growth leads to 0.14 and 0.26 p.p. higher sales growth in periods $\tau = 0$ and $\tau = 1$, statistically significant at the 10% and 1% levels, respectively. The Kleibergen-Paap rk LM statistic is 7.57, which again easily surpasses the critical value necessary to reject that the correlation matrix between endogenous and exogenous regressors has less than full rank. For physical production, we find that a 1 p.p. increase in foreign demand growth leads to 0.16 and 0.12 p.p. higher growth in periods $\tau = 1$ and $\tau = 2$, statistically significant at the 1% and 5% levels, respectively. The Kleibergen-Paap rk LM statistic is 7.96. For production and sales, we can reject pre-trends.²¹ Unit values increase slightly, especially in period $\tau = 0$, though the point estimate is only marginally significant. Evaluated at mean growth rates, these estimates indicate that a 1 p.p. increase in foreign demand growth leads to about 7% higher sales and production growth.

For CO₂ emissions, with a sample of 8,046 firm-product-year observations, across 1,539 firm-products and 1,030 firms, we find in panel b) that a 1 p.p. increase in foreign demand growth leads to 0.15 and 0.05 p.p. higher emissions growth in periods $\tau = 1$ and $\tau = 2$. The former estimate is statistically significant at the 1% level, while the latter is only marginally significant (p-value 0.25). The Kleibergen-Paap rk LM statistic is 7.99. Again, we can rule out pre-trends. Evaluated at the mean firm-product CO₂ emissions growth, the estimate (in $\tau = 1$) implies 5% higher growth rate as a result of a 1 p.p. increase in foreign demand growth.

Finally, panel c) presents the results for emission intensity at the firm-product level, with samples of 7,750 and 8,032 observations for CO₂/V and CO₂/Q. We estimate that a 1 p.p. increase in foreign demand growth leads to 0.17 p.p. lower growth in emission intensity in value in period $\tau = 0$ (significant at the 1% level), and to 0.06 p.p. lower growth in emission intensity in quantity in period $\tau = 1$ (significant at the 1% level). Kleibergen-Paap rk LM statistic are 7.72 and 7.89, respectively. Evaluated at mean growth rates, baseline estimates imply 7% and 10% lower emission intensity growth for CO₂/V and CO₂/Q as a result of a 1 p.p. increase in foreign demand. The impact on emission intensity in quantity

²¹Even with a non-trivial impact from lead shocks for sales, the negative sign is hard to reconcile with a differential pre-trend explanation of the post-shock results.

Figure 2: Firm-product-level results, Instrumental Variables

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (6) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for total output (Q) and total CO_2 emissions (CO_2), and panel c) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm-product level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{jt-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-product-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 7.64 (for V) to 8.07 (CO_2). Number of observations range from 7,835 (for V) to 8,046 (CO_2).

confirms that technological adjustments contribute to lower average firm-level emission intensity.²² This constitutes the first empirical evidence of firms adjusting endogenously their technology, hence their emission intensity, at the product level with trade shocks

²²We also explore long difference specifications to allow more time for adjustment, as in the climate change literature (Dell et al., 2012; Burke & Emerick, 2016). See Table A.1 for results. Signs and magnitudes are similar, but with smaller sample size, estimates are only marginally significant for emission intensity in quantity.

that we are aware of. This result, and all other firm-product-level results, are robust to excluding nonmetallic minerals (Fig. A.10), and alternatively suppressing the top and bottom 2% of firm-year outcome values and foreign demand shocks (Fig. A.11).

5 Heterogeneous Impacts

In this section, we study heterogeneous impacts from foreign demand shocks on single-product versus multi-product firms, on large vs small firms, on clean vs polluting firms within a sector, and on firms belonging to heavily polluting industries vs belonging to cleaner industries.

5.1 Multi-product versus single-product firms

Firms that supply multiple products may adjust their average emission intensity by changing their product mix. In fact, if each product within a firm generates a specific amount of CO₂ emissions per unit of output, then adjusting product mix can affect firm emission intensity without any investment made at the firm-product level. However, multi-product firms may also be intrinsically different from single-product firms: multi-product firms are often larger, more productive, and facing lesser liquidity constraints. We defined single-product firms as firms that only produce a single product over the entire period of analysis. We test for heterogeneous responses to foreign demand shocks for single-product and multi-product firms by running equations 5) and (6) for each sub-sample.

Panels A and B in Table 3 report the results from these regressions for the sub-samples of multi-product vs single-product firms, respectively, while focusing only on the contemporaneous shock ($\tau = 1$). Indeed, we have found earlier that most of the firms' response is contemporaneous. We only report results for total sales (V), output in quantity (Q), emission intensity in value (CO₂/V) and in quantity (CO₂/Q) both at the firm level and at the firm-product level, since we search for heterogeneity in firms' response that can impact their emission intensity. Overall, we do not find that multi-product firms behave significantly differently to single-product firms. The firm level response in emission intensity is negative but not significant for both sub-samples, whereas the firm-product response in emission intensity is negative and statistically significant at the 5% level only for CO₂/V for multi-product firms. This suggests that multi-product firms could have a stronger price effect that will influence the decline in emission intensity in value, but we cannot conclude

that single-product and multi-product firms show heterogeneous responses in technology upgrading.

5.2 Heterogeneity in size

Large firms may be more prone to make technological investments as they face lesser financial constraints or have better access to credit. We test for heterogeneous response to foreign demand shocks by interacting these shocks with a dummy variable identifying firms that have average annual total sales above the median within their industry (defined as 2-digit Prowess code of the main product category for each firm). Panel C in Table 3 reports the results from estimating equations (5) and (6) for contemporaneous shocks ($\tau = 1$) and considering heterogeneity in size. We find that most of our outcome variables, even total sales and production, lose their statistical significance when we contrast small versus large firms, except firm-product emission intensity in quantity for which we observe heterogeneous responses (significant at the 1% level). Results in column 8 of panel C indicate that emission intensity reductions at the firm-product level are driven by below-median-sales firms.

5.3 Heterogeneity in emission intensity

Finally, we explore heterogeneity in terms of emission intensity either across firms within a sector or across sectors. Panel D of Table 3 reports the results from estimating equations (5) and (6) for contemporaneous shocks ($\tau = 1$) and interacting foreign demand shocks with a dummy variable identifying firms that have average annual total emission intensity (in value) above the median within their industry (defined as 2-digit Prowess code of the main product category for each firm). Panel E reports the results from interacting demand shocks with a dummy variable identifying industries (2-digit Prowess code as well) with average annual total emission intensity (in value) above the median. In either case, we do not find any significant heterogeneous response in emission intensity. We observe a significant contrast only for production at the firm level and sales at the product level for clean vs dirty firms within an industry: dirty firms respond less strongly to foreign demand shocks.

Notes: We report estimates of β_1 from equation (5) in columns 1 to 4 and from (6) in columns 5 to 8. Panel A uses a sub-sample of multi-product firms, and panel B of single-product firms. Panel C reports results on firms being larger than the median in size (denoted 'large'), panel D on firms being dirtier than the median within their own sector (denoted 'dirty'), and panel E on firms being part of a dirtier sector (denoted 'dirtysector'). Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels.

6 Counterfactuals

To quantify the impacts of trade shocks over the period 1995 - 2011 and assess the relative magnitude of the different channels through which they influenced emissions, we build counterfactual emission growth rates firm by firm or product by product and compare them to observed growth rates. We first identify the full trade effect on emissions growth by comparing observed growth rates with equivalent metrics that counterfactually set foreign demand growth to 0. We then decompose the contribution of a scale effect (due to the growth in total sales), an emission intensity effect, and an export sales effect.

6.1 Computing Counterfactual Growth Rates

To reveal the magnitude of the full trade effect – that is, the overall causal impact of foreign demand shocks on CO₂ emissions growth in Indian firms – we compute counterfactual growth rates year by year for firms and firm-products as

$$\Delta Y'_{ikt,t-1} = \Delta Y_{ikt,t-1} - \sum_{\tau=0}^2 \widehat{\beta}_{\tau} * \Delta FD_{it-\tau,t-1-\tau} \quad (7)$$

$$\Delta Y'_{ijkt,t-1} = \Delta Y_{ijkt,t-1} - \sum_{\tau=0}^2 \widehat{\beta}_{\tau} * \Delta FD_{jt-\tau,t-1-\tau} \quad (8)$$

where $\widehat{\beta}_{\tau}$ are the instrumental variables estimates from Figures 1 and 2. We consider two years of lagged trade shocks and no leads; hence, the period of analysis runs from 1998 to 2011. For the full trade effect, Y corresponds to CO₂ emissions, but we also need to compute the same counterfactual growth rates (7) and (8) for other outcome variables, such as total, domestic and export sales, and production. Denoting the counterfactual emissions growth rates obtained from (7) and (8) by $\Delta CO2'_{ikt,t-1}$ and $\Delta CO2'_{ijkt,t-1}$, we can measure the *full trade effect* – which includes a scale effect and an emission intensity effect (encompassing technology and product mix effects at the firm level, and reflecting only technology at the firm-product level) – by comparing these counterfactual growth rates to the observed growth rates.

Next, we compute counterfactual emissions growth rates under different scenarios to decompose the contribution of each channel. In the first scenario, we assume that trade shocks result only in a scale effect measured in physical output growth. Implicitly, we thus assume that any improvement in emission intensity in quantity observed over the period

would have happened anyway. To do so, we compute counterfactual levels of an outcome variable Y by inverting the Davis-Haltiwanger growth rate:

$$Y'_{ikt} = Y'_{ik,t-1} * \frac{2 + \Delta Y'_{ikt,t-1}}{2 - \Delta Y'_{ikt,t-1}}, \quad Y'_{ijkt} = Y'_{jik,t-1} * \frac{2 + \Delta Y'_{ijkt,t-1}}{2 - \Delta Y'_{ijkt,t-1}}, \quad (9)$$

starting at observed base year t_0 levels, and then proceeding iteratively year after year.²³ Using the counterfactual levels for output (Q'_{ikt} and Q'_{ijkt}) obtained from (9), we compute counterfactual CO₂ levels as:

$$CO2''_{i,t} = \left(\frac{CO2}{Q} \right)_{it} * (Q'_{it}), \quad CO2''_{ij,t} = \left(\frac{CO2}{Q} \right)_{ij,t} * (Q'_{ij,t}), \quad (10)$$

where $(CO2/Q)_{it}$ and $(CO2/Q)_{ij,t}$ are the observed emission intensities in quantity for firm i and firm-product ij in year t . After computing these levels (10) for all years, we take the Davis-Haltiwanger growth rates. The difference between these counterfactual growth rates and the observed growth rates identifies the *scale effect* of trade measured in quantity. Additionally, the difference between these counterfactuals and the full trade effect counterfactuals ($\Delta CO2'_{ikt,t-1}$ and $\Delta CO2'_{ijkt,t-1}$) identifies the emission intensity effect in quantity.

In the second scenario, we assume that trade shocks result only in a scale effect measured in value. We proceed as before and compute the following counterfactual levels:

$$CO2'''_{i,t} = \left(\frac{CO2}{V} \right)_{it} * (V'_{it}), \quad CO2'''_{ij,t} = \left(\frac{CO2}{V} \right)_{ij,t} * (V'_{ij,t}), \quad (11)$$

where $(CO2/V)_{it}$ and $(CO2/V)_{ij,t}$ are the observed emission intensities in value in t , and V'_{it} and $V'_{ij,t}$ are counterfactual total sales computed from (9). Comparing the resulting counterfactual growth rates to observed growth rates identifies the scale effect of trade in value, while comparison to $\Delta CO2'_{ikt,t-1}$ and $\Delta CO2'_{ijkt,t-1}$ identifies the emission intensity in value effect. These measures obviously include price effects, but they are useful benchmarks to consider for settings in which quantities are unobserved.

The third scenario aims at isolating the effect of trade-induced export growth on emissions. For this scenario, we assume that trade only impacts export sales, thereby attributing all domestic sales growth and emission intensity in value growth to factors other than

²³These measures explode as the counterfactual growth rate approaches -2 or 2, so we censor growth rates at -1.95 and 1.95.

foreign trade. As exports are only observed at the firm level, we compute

$$CO2_{i,t}'''' = \left(\frac{CO2}{V} \right)_{it} * (EXV_{it}' + DOMV_{it}), \quad (12)$$

where $(CO2/V)_{it}$ and $DOMV_{it}$ are observed emission intensity in value and domestic sales for firm i in year t , and EXV_{it}' is counterfactual export sales computed from (9). We then compute growth rates. Comparing these counterfactuals to observed growth rates identifies the *export sales effect* of trade.

6.2 Results

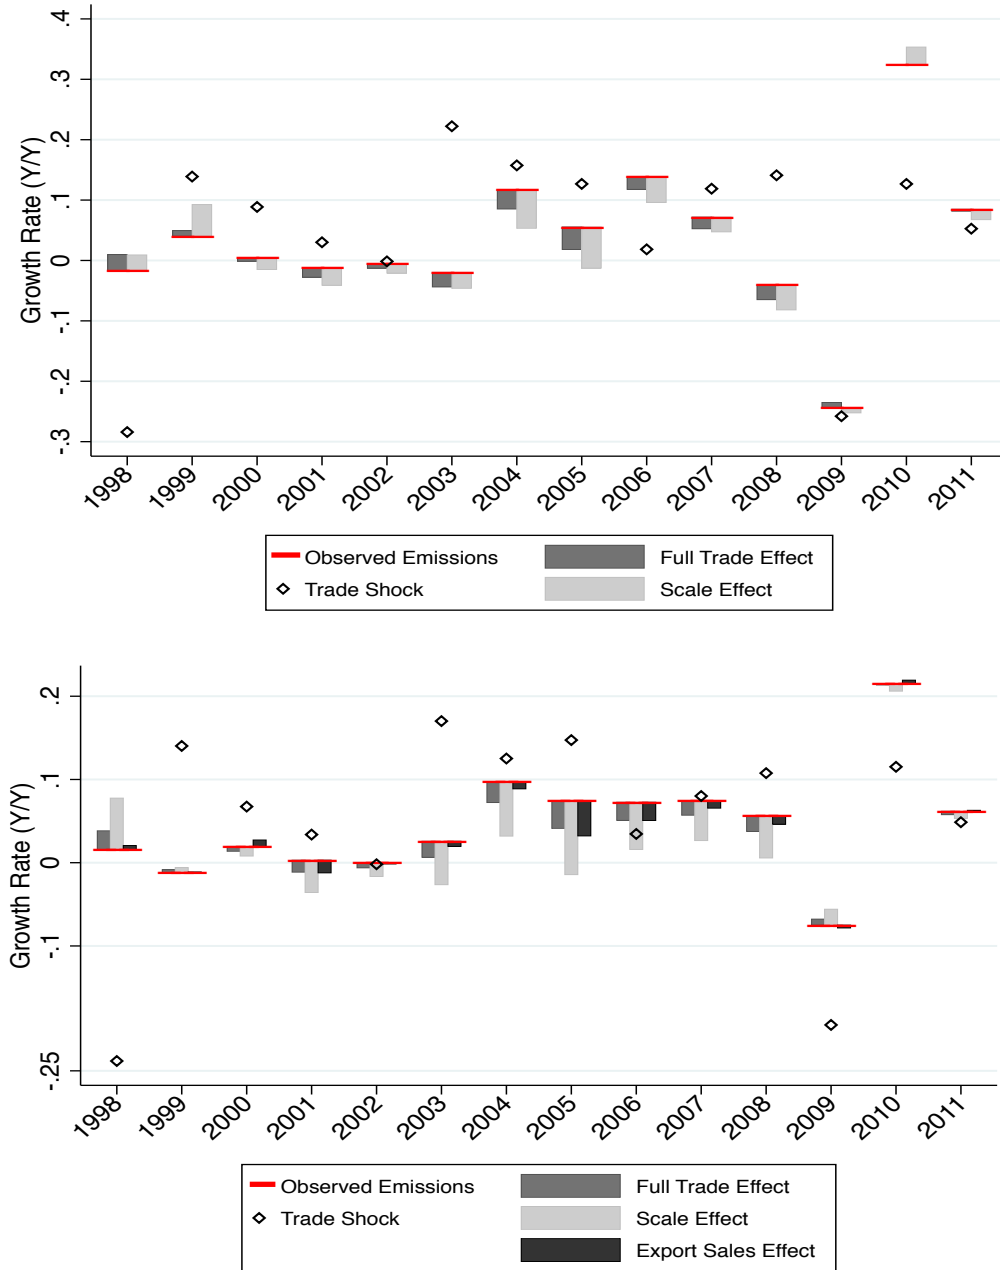

Figure 3 reports graphically the decomposition of the different firm-level channels for quantity (top) and value (bottom). To aggregate over firms, we compute sales weighted average growth rates year by year. Observed emission growth rates are reported by horizontal red lines. Average trade shocks are reported with diamonds. Dark gray bars indicate the full trade effect, i.e. $\Delta CO2_{it,t-1} - \Delta CO2'_{it,t-1}$, which is positive if the bar is below the corresponding red line and negative otherwise. Light gray bars indicate the scale effect of trade, i.e. the difference between observed trade growth and $\Delta CO2''_{it,t-1}$ (top) and $\Delta CO2''''_{it,t-1}$ (bottom). Black bars indicate the export sales effect of trade, i.e. $\Delta CO2_{it,t-1} - \Delta CO2''''_{it,t-1}$.

In the top panel of Figure 3, we see that trade shocks strongly influence emissions growth at the firm level. Observed emissions growth was mostly flat from 1998 to 2003, while it increased significantly between 2004 and 2007 with an annualized rate of 9.5%, mostly mirroring foreign demand growth (10% per year). The financial crisis of 2008-2009 then substantially reversed emissions growth, before the recovery in 2010. Counterfactual emissions growth broadly followed observed emissions growth in terms of macro swings, but the year-by-year comparisons reveal a substantial impact from trade. For instance, between 2004 and 2007, emissions would have grown at an annualized rate of only 6.8% without trade shocks, and trade shocks increased this growth rate by 2.7 p.p. annually. Over the whole period, the full trade effect represents an increase in emissions growth rates of 1.1 p.p. on average each year, which amounts to 28% of the total growth rate.²⁴

Next, we decompose the full trade effect into firm-level scale and technique effects. In the top panel of Figure 3, we see some significant differences between the full trade effect (dark gray bars) and the scale effect (light gray bars) year by year. For example, in 2004,

²⁴Over the whole period, the annualized growth rate in observed emissions was 3.6%, compared to annualized growth rate in counterfactual emissions of 2.5%.

Figure 3: Firm Level Channels, Quantity (top) and Value (bottom)

Notes: Red lines indicate the observed weighted average growth rate in CO₂ emissions. Dark gray bars indicate the full impact of foreign demand shocks including contemporaneous shocks and two years of lags. Light gray bars indicate the average scale effect, i.e., change in emissions due to changes in output quantity (top) or in total sales (bottom). Black bars indicate the average export scale effect, ruling out any impact on domestic sales. Diamonds indicate the weighted average foreign demand shock experienced by firms in a given year.

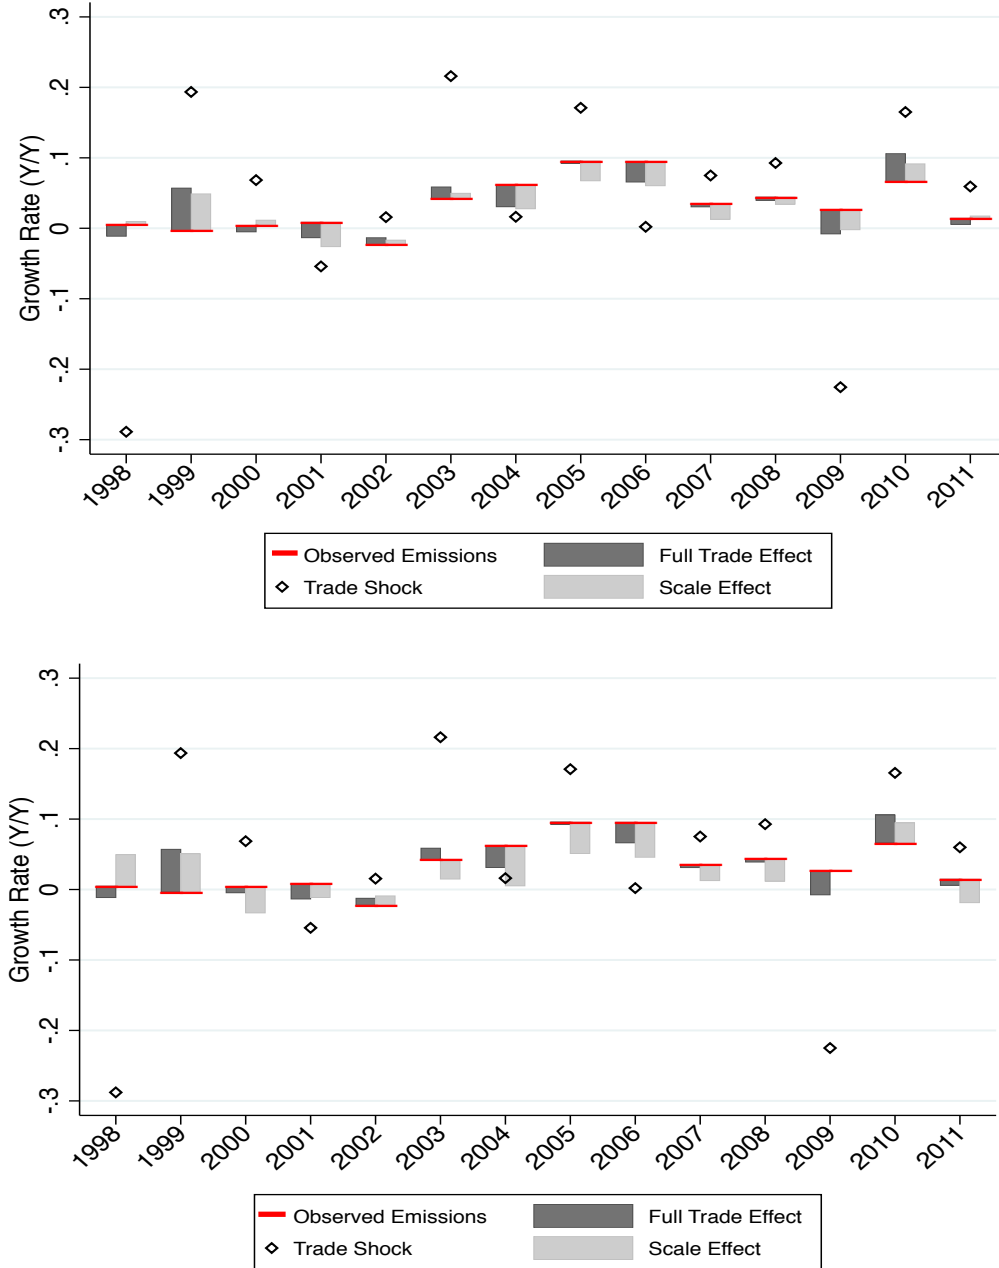

observed emissions grew at 11.8%, counterfactual emissions removing the full impact of trade shocks grew at 8.5%, while counterfactual emissions under the first scenario grew only at 5.3%. The resulting scale effect pushed emissions growth up by 6.5 p.p., whereas the trade-induced emission intensity effect lowered emissions growth by 3.2 p.p. Adding the two effects together yields a full trade effect of 3.3 percentage points. Averaging over the whole period, we find that the scale effect increased emissions growth rates by 1.8 p.p. annually, while the emission intensity effect reduced emissions growth rates by 0.74 p.p. annually, amounting to 50% and -21% of the observed annual growth rate, respectively.

In the bottom panel of Figure 3, we assess the corresponding measures expressed in value. This allows us to assess the importance of the export sales channel separately from the domestic sales channel. Note that observed emissions growth and trade shocks are not exactly the same as in the top panel due to differences in the sample and weighting metrics, but the patterns are very similar. Averaging over the whole period, we estimate that the trade-induced scale effect in value increased emissions growth by 2.6 p.p. per year, accounting for 58% of the observed growth rate, while the trade-induced emission intensity effect in value decreased emissions growth by 1.6 p.p. per year, slowing the observed growth rate by 36%. On net, foreign demand shocks increased the emissions growth rate by 0.98 p.p., or 22% of the observed rate.

Additionally, we find that export sales growth raised emissions by 1.1 p.p. annually. For high foreign demand growth years, this effect can be quite large. For example, in 2005, we estimate that the export sales channel contributed 4.2 percentage points to the growth rate. In magnitude, the export sales effect is very close to the full trade effect on average, which indicates that the emission intensity effect in value almost perfectly offsets the domestic sales effect. However, even if emissions seem to increase almost 1-for-1 with exports on average, this relationship does not hold each year: for instance, the export sales effect is larger than the full trade effect in 2005, smaller in 2004, and even of opposite sign in 2009. Export sales alone are thus not sufficient to assess the full environmental impact of trade shocks.

Figure 4 reports graphically the contributions of the full trade effect, scale effect, and technique effect at the product level in quantity (top) and value (bottom), along with weighted-average foreign demand growth (diamonds). In the top panel, we find that foreign demand growth increased the emissions growth rate via the scale effect by 0.61 p.p. and slowed emissions growth rate via the technique effect by 0.35 p.p, for an overall trade effect of 0.26 p.p.. Hence, the technique effect mitigates 57% of the scale effect, on average. At

Figure 4: Product Level Channels, Quantity (top) and Value (bottom)

Notes: Red lines indicates the observed weighted average growth rate in CO_2 emissions. Dark gray bars indicate the average full impact of foreign demand shocks including contemporaneous shocks and two years of lags. Light gray bars indicate the average scale effect, i.e., change in emissions due to changes in output quantity (top) or in total sales (bottom). Diamonds indicate the weighted average foreign demand shock in the sample in a given year.

an average annual growth rate of 3.36% in the sample, the scale, technique, and overall impacts of trade shocks amount to 18.1%, -10.3%, and 7.7% of the observed growth rate,

respectively.

In the bottom panel of Figure 4, we find similar magnitudes from the full impact of trade, but with output denominated in value, we see that price effects magnify both the scale and technique effects. Averaged over the whole sample, we estimate that foreign demand growth raised the emissions growth rate via the scale effect by 1.3 p.p. and slowed emissions growth rate via the technique effect by 1.1 p.p, for an overall trade effect of 0.26 p.p.. Hence, the technique effect mitigates 80% of the scale effect, on average. At an average annual growth rate of 3.38% in the sample, the scale, technique, and overall impacts amount to 38.7%, -31.0%, and 7.7% of the observed growth rate, respectively. Comparing the top and bottom panels, we see that had we ignored price effects, we would have overestimated the scale effect by a factor of 2 and the technique effect by a factor of 3, on average.

7 Conclusion

Increased participation of developing countries in global markets raises concerns about the environmental costs of globalization. If emissions grow 1-for-1 with export sales, then the recent rise in exports from developing countries signifies a substantial growth in emissions from these countries as well. If foreign demand growth triggers endogenous reductions in emission intensity, then the overall impact on emissions could be less than the growth in export sales. But if domestic sales rise with export sales too, then the growth in emissions could be more than the growth in export sales. Additionally, identifying the channels of adjustment is difficult when output is aggregated across multiple products and denominated in value.

In this paper, we find that over the period 1998 - 2011, foreign demand shocks stimulated substantial growth in firm-level CO₂ emissions in Indian manufacturing firms via the output scale effect, but that an endogenous technique effect mitigated roughly half of this effect. A substantial fraction of the scale effect owes to increased domestic sales. These results confirm that export sales growth is insufficient for understanding emissions growth in general. However, in our sample, the domestic sales effect is roughly the same magnitude as the emission intensity effect, so the export sales effect approximates the full trade effect well on average. We emphasize that there is no theoretical reason why the magnitudes of these effects should be equal, so there is no reason that these effects offset each other. In fact, year by year, we find substantial difference between the trade-induced export effect

and the full trade effect. It is just that these differences wash out in the average.

At the firm-product level, we present the first evidence we are aware of that emission intensity *in quantity* falls with trade shocks. Contrary to previous research, this emission intensity reduction cannot be explained by price effects or product mix, since both are absent by construction. This technological channel has been discussed in the literature, but we are the first – to our knowledge – to document a case of its existence. In terms of magnitude, we find that this trade-induced technological channel slowed firm-product-level emissions growth rates by 0.35 percentage points and mitigated about half of the scale effect. We emphasize that the existence of a technological channel does not preclude the simultaneous existence of a product-mix channel. Additionally, had we only observed output denominated in value, we would have overestimated the technological channel by approximately 200%.

The results indicate that researchers should not hold emission intensity fixed when analyzing trade’s impact on emissions, nor should they assume that markets are entirely segmented. While the emission intensity effect mitigates about half of the scale effect in our Indian manufacturing context, CO₂ emissions still rise with foreign demand growth, validating concerns that trade exacerbates environmental externalities.

Appendix

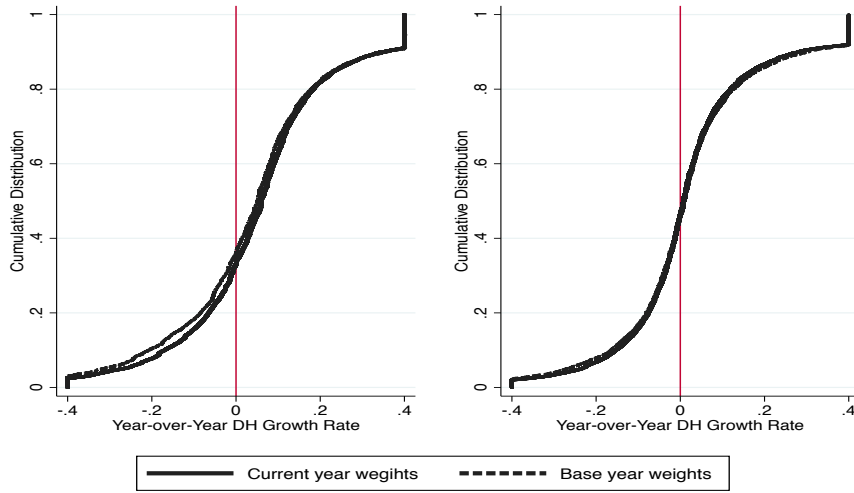

A Additional Results

Figure A.1: Foreign Demand Over Time

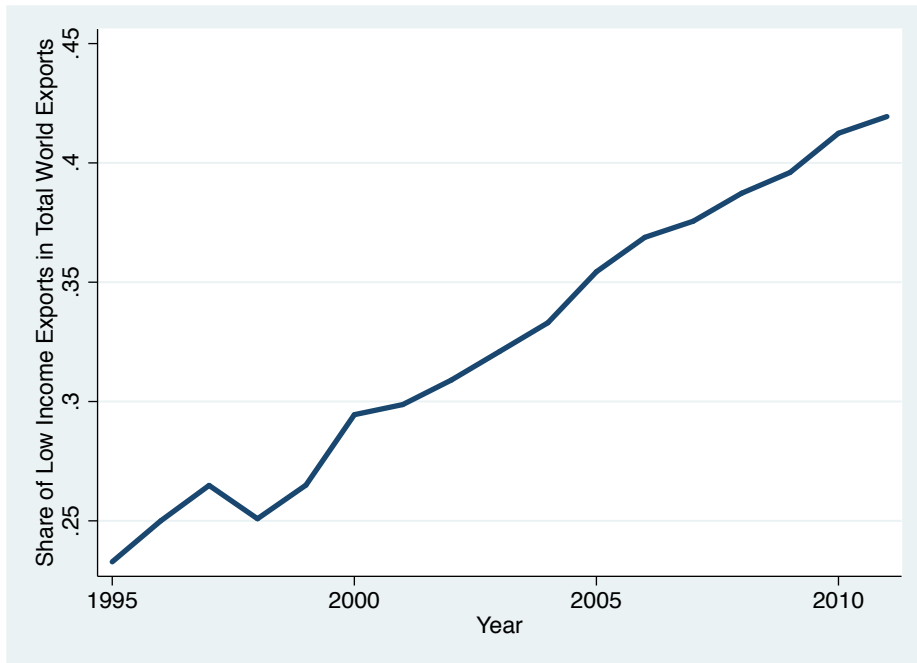

Notes: Figure reports weighted average foreign demand (FD_{jt}) indices by industry where goods are classified by HS rev 1996 (A) and Prowess product codes (B).

Figure A.2: Foreign Demand Variation

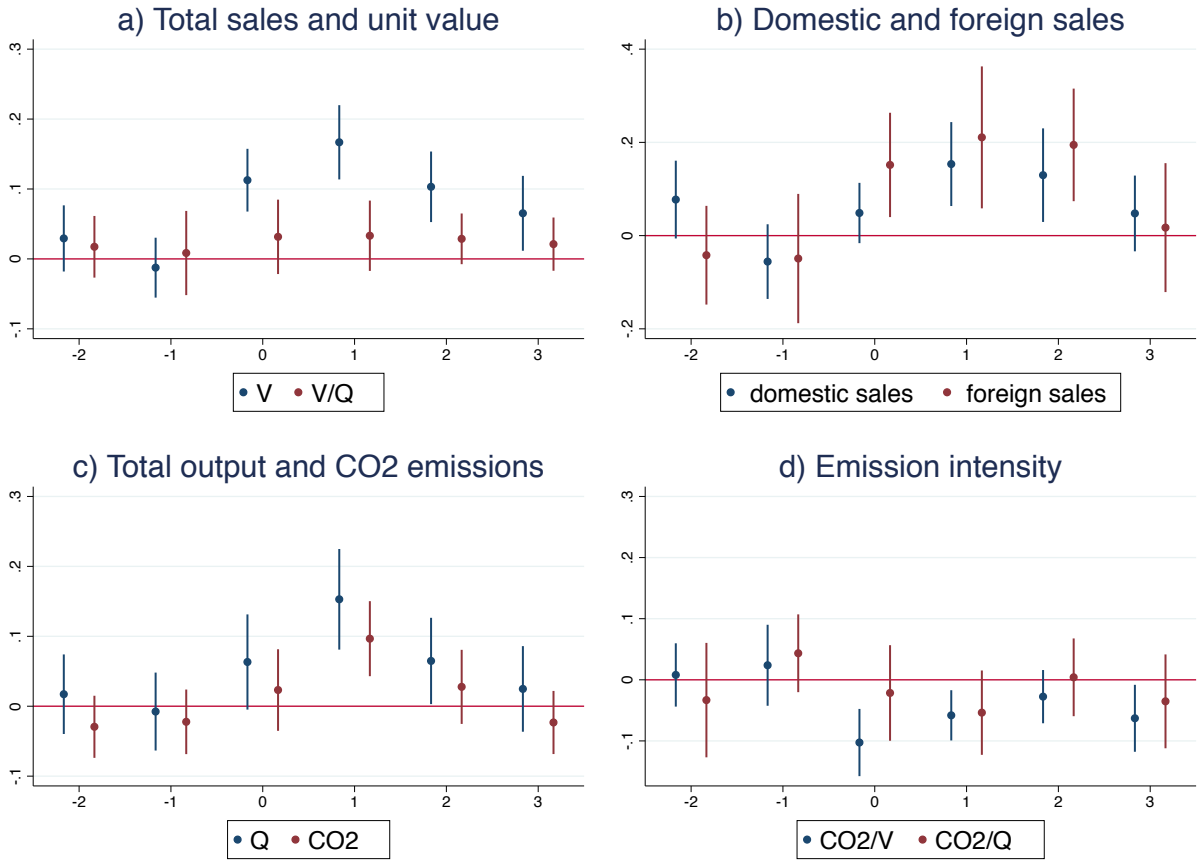

Notes: The Davis-Haltiwanger (DH) growth rate and residual growth rate are computed at the product level (3,276 products). Right panel plots residuals after regressing $\Delta FD_{jt,t-1}$ on product code fixed effects and industry-by-year fixed effects. In both panels, growth rates are truncated at -40% and 40% for ease of viewing.

Figure A.3: Developing World Export Share Over Time

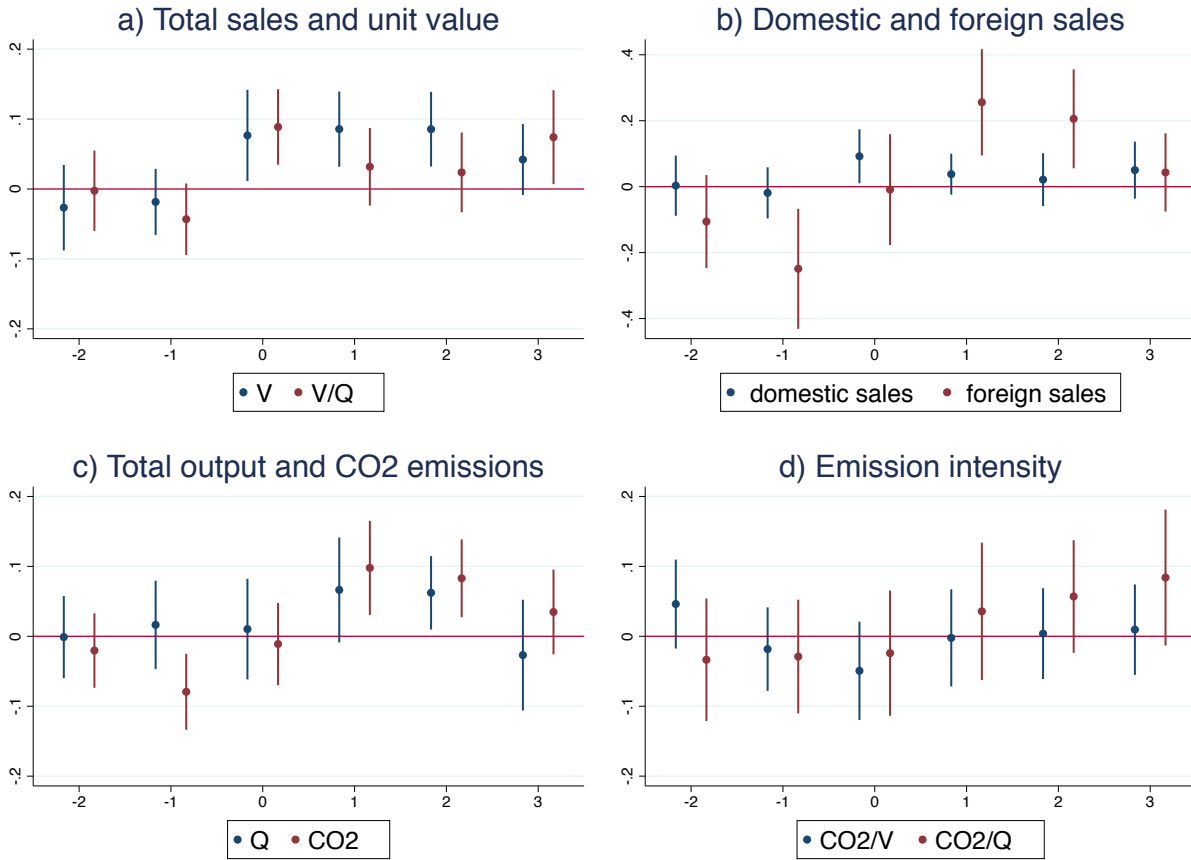

Notes: Computed from BACI Export Data set. Developing Country is defined as any country not defined by the World Bank in 2006 as “High Income OECD” or “High Income Other”.

Figure A.4: Firm-level results, Reduced Form

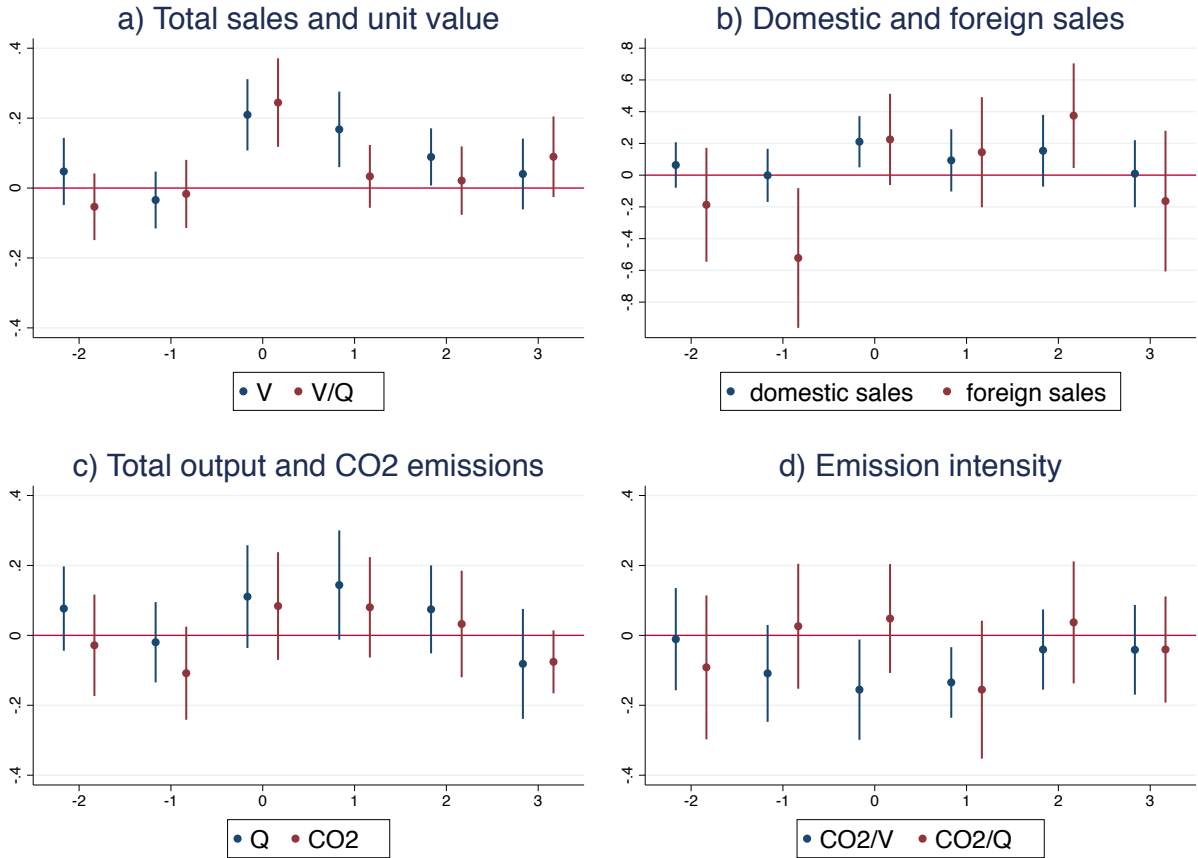

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO₂ emissions (CO₂), and panel d) for emission intensity in value (CO₂/V) and in quantity (CO₂/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from OLS regressions of dependent variables on base-year weighted instruments $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Number of firm-year observations range from 11,107 (for CO₂/Q) to 36,157 (for V).

Figure A.5: Firm-level results, OLS

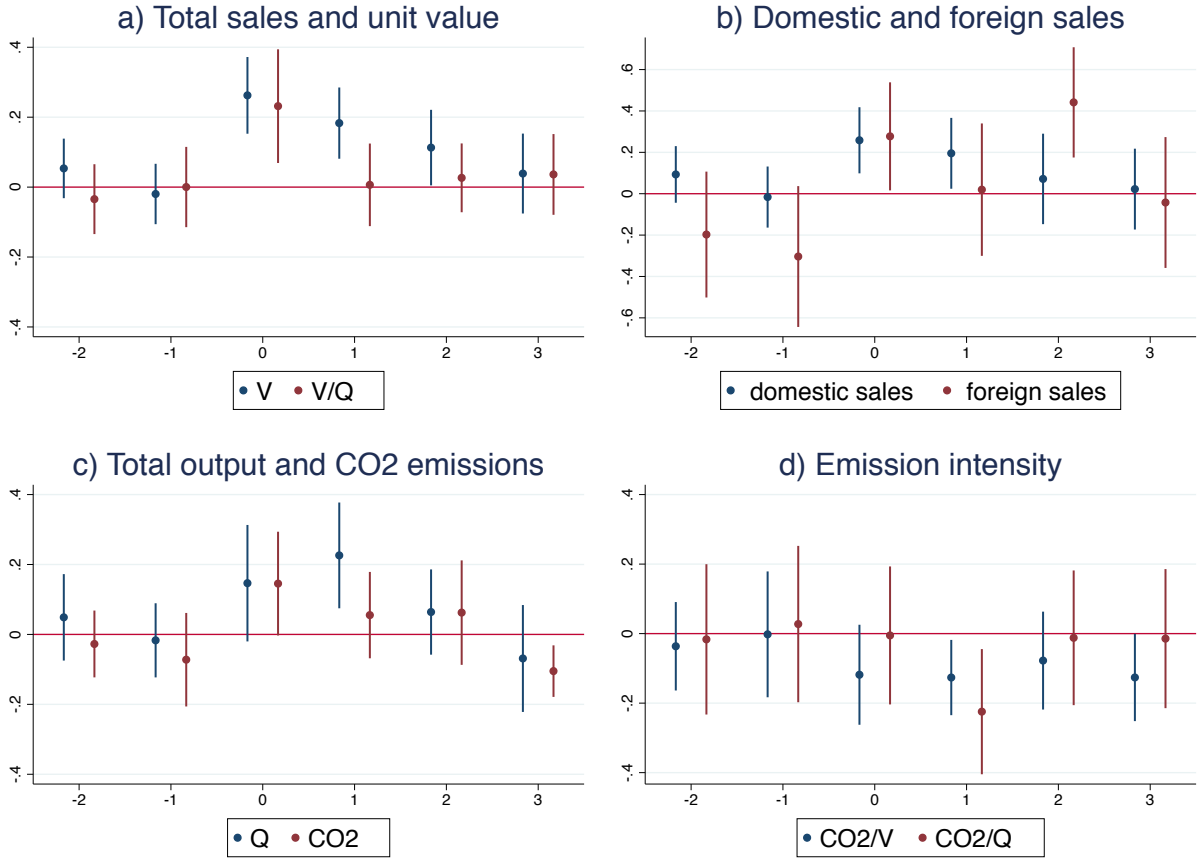

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO₂ emissions (CO₂), and panel d) for emission intensity in value (CO₂/V) and in quantity (CO₂/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from OLS regressions of dependent variables on contemporaneous foreign demand shocks. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Number of firm-year observations range from 6,582 (for CO₂/Q) to 21,183 (for V).

Figure A.6: Firm-level results, Excluding top/bottom 2%

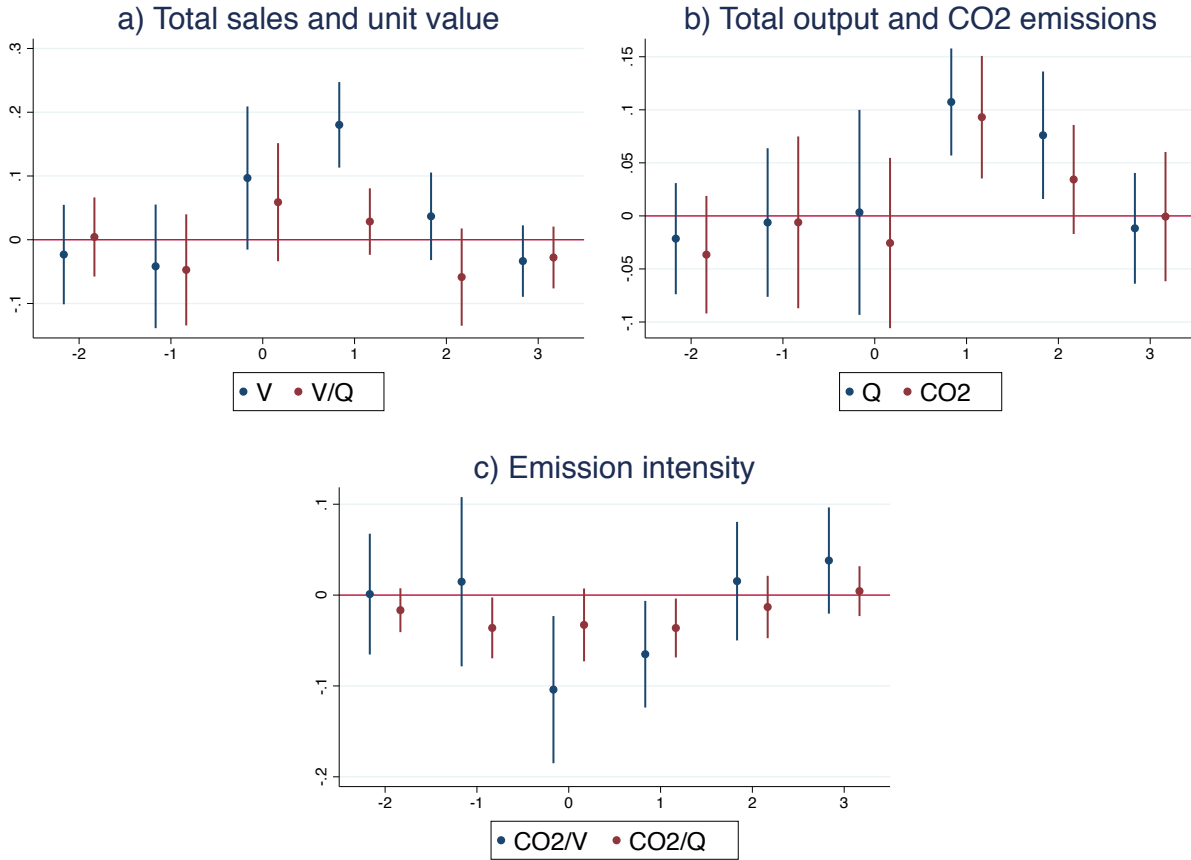

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO₂ emissions (CO₂), and panel d) for emission intensity in value (CO₂/V) and in quantity (CO₂/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 2% of firm-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 10.66 (for CO₂/Q) to 19.65 (for export value). Number of firm-year observations range from 5,704 (for CO₂/Q) to 18,134 (for V).

Figure A.7: Firm-level results, Excluding Nonmetallic Minerals

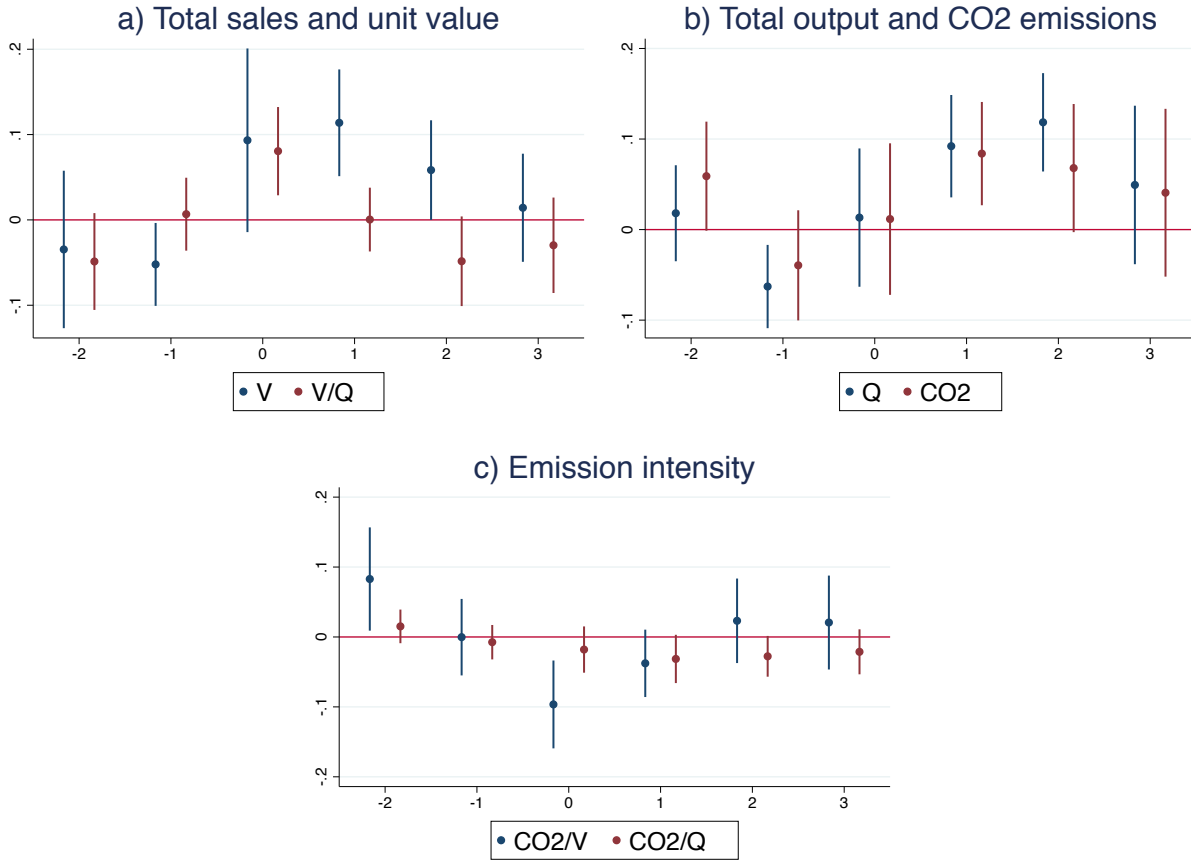

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO₂ emissions (CO₂), and panel d) for emission intensity in value (CO₂/V) and in quantity (CO₂/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 9.86 (for CO₂/Q) to 17.39 (for V). Number of firm-year observations range from 6,048 (for CO₂/Q) to 18,900 (for V). Sample excludes Nonmetallic Minerals.

Figure A.8: Firm-product level, Reduced Form

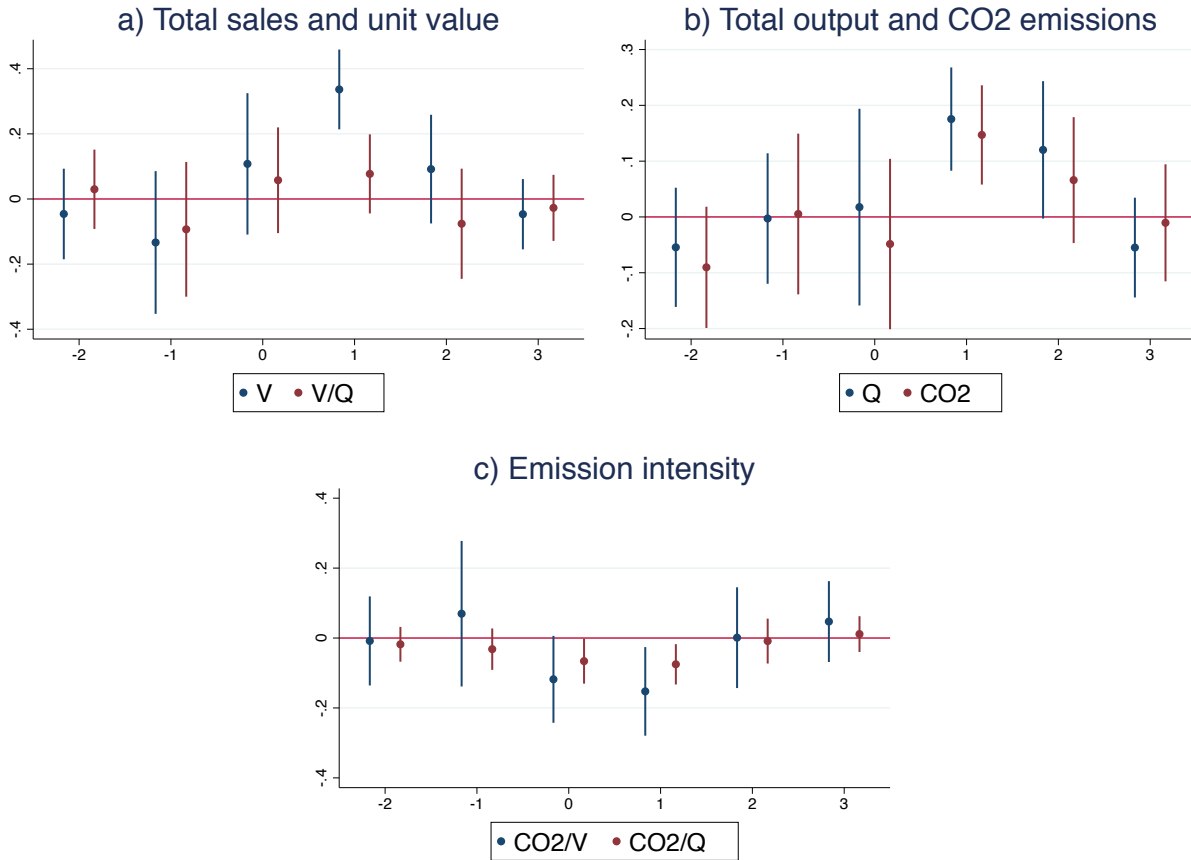

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO_2 emissions (CO_2), and panel d) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Number of observations range from 7,835 (for V) to 8,046 (CO_2).

Figure A.9: Firm-product level, OLS

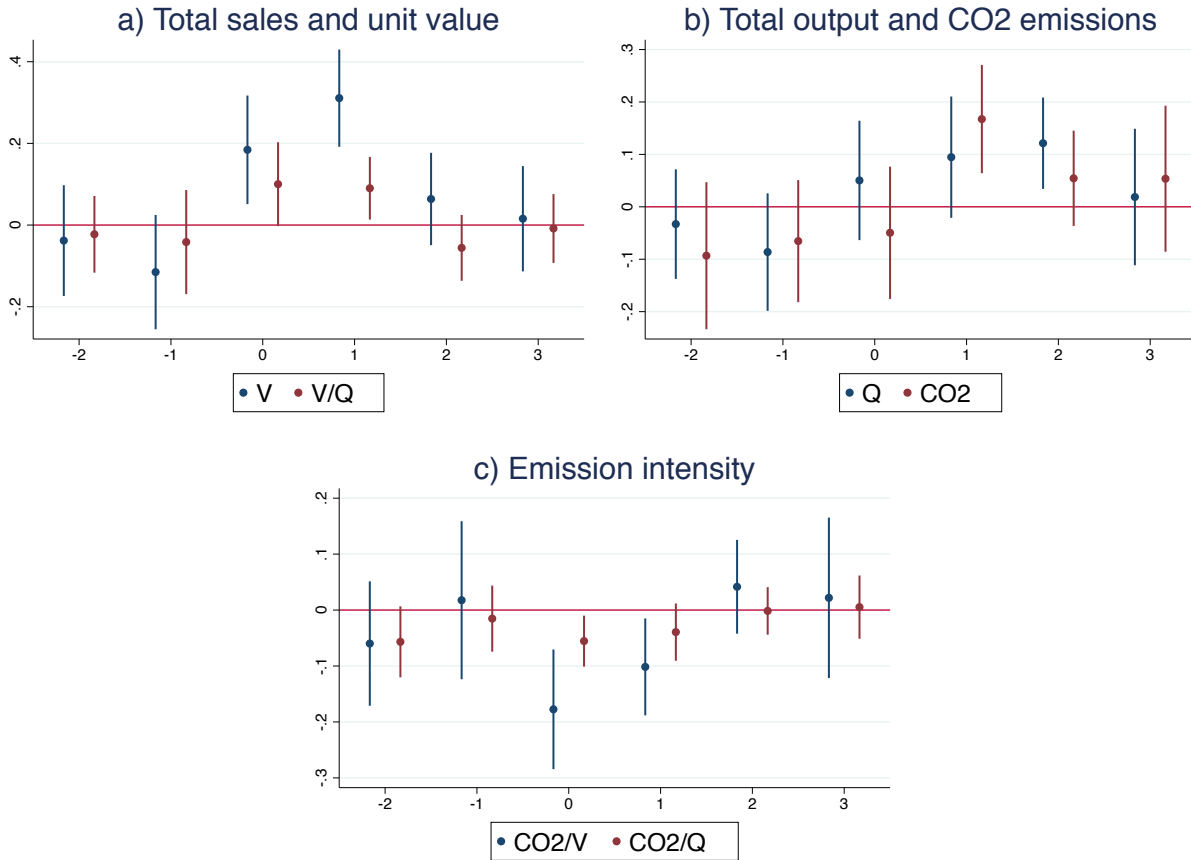

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO_2 emissions (CO_2), and panel d) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Number of observations range from 7,835 (for V) to 8,046 (CO_2).

Figure A.10: Firm-product level, Excluding Nonmetallic Minerals

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO_2 emissions (CO_2), and panel d) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 1% of firm-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 8.07 (for CO_2/Q) to 8.41 (V/Q). Number of firm-year observations range from 7,213 (for CO_2/V) to 7,503 (CO_2).

Figure A.11: Firm-product level, Excluding top/bottom 2%

Notes: Estimates of coefficients β_τ for $\tau = -2, \dots, 3$ from equation (5) are reported graphically. Panel a) reports these coefficients for total sales (V) and unit value (V/Q), panel b) for domestic and foreign sales, panel c) for total output (Q) and total CO_2 emissions (CO_2), and panel d) for emission intensity in value (CO_2/V) and in quantity (CO_2/Q), all at the firm level. The x-axis represent the value of τ , the dots the point estimates of β_τ , the bar the 95% confidence intervals. Estimates are obtained from instrumental variable regressions where endogenous trade shocks are instrumented by $\Delta Z_{it-\tau, t-1-\tau}$. Standard errors are clustered at the 4-digit industry level. Top and bottom 2% of firm-year outcomes and trade shocks have been trimmed. Kleibergen-Paap rk LM statistics range from 9.41 (for V/Q) to 9.87 (for CO_2/Q). Number of firm-year observations range from 6,996 (for CO_2/V) to 7,241 (for Q).

Table A.1: Long Difference Results at the Firm-Product Level

<i>Dep Var:</i>	ΔV	ΔQ	$\Delta(V/Q)$	ΔCO_2	$\Delta(CO_2/V)$	$\Delta(CO_2/Q)$
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Panel A: 3-year intervals</i>						
$\Delta FD_{jt,t-3}$	0.176*** (0.044)	0.113*** (0.040)	0.050* (0.030)	0.115*** (0.043)	-0.056 (0.037)	-0.006 (0.025)
# Obs	2850	2931	2845	2932	2816	2922
<i>Panel B: 5-year intervals</i>						
$\Delta FD_{jt,t-5}$	0.231*** (0.061)	0.143*** (0.054)	0.095** (0.042)	0.092 (0.057)	-0.122** (0.051)	-0.056 (0.035)
# Obs	1113	1153	1113	1155	1099	1158

Notes: Table presents long difference estimates from regression (6) for contemporaneous shocks only. All explanatory and dependent variables are computed as the Davis-Haltiwanger growth rate for 3-year intervals (panel A) or 5-year intervals (panel B). Top and bottom 1% of outcomes and trade shocks have been trimmed. Asterisks indicate statistical significance at the 1% ***, 5% **, and 10% * levels.

B Data Appendix

In this appendix, we discuss individuating products in the output data, computing CO₂ emissions from energy-use data, merging product-specific emission intensity to product-specific outputs, diagnostic checks on the product-specific emissions calculations, and constructing trade shocks from trade data. The first four steps rely on our previous work (Barrows & Ollivier, 2018). Hence, we provide summaries of the procedures here and direct the reader to Appendix A of Barrows & Ollivier (2018) for more details. As the construction of the trade shock is novel, we describe it in more depth.

B.1 Individuating Products in the Output Data

Firms report value and quantity of sales each year individuated by text descriptions (e.g. “t-shirts”). CMIE assigns each product string a single 16-digit product classification code, which we will use to map to trade shocks. However, the CMIE codes are not ideal for individuating products. First, CMIE sometimes assigns different product codes to the same text description over time. Second, CMIE sometimes assigns the same product codes to multiple text descriptions within the same firm-year. Our assumption is that if the firm separately reports output information for two (potentially closely related) product descriptions, then we should treat them as different products, even if CMIE does not distinguish between them in terms of product codes. Hence, we take the firm-supplied product string name as the identifier of a firm-product.

As described in Barrows & Ollivier (2018), an issue with the output data is that output units are not always constant within firm-product over time. We attempt to standardize units as much as possible, but then drop any observations from the analysis which we cannot compute in constant units. See Barrows & Ollivier (2018) for more details.

B.2 Computing Emissions from Energy-Use Data

While firms in Prowess do not report emissions directly, we can compute CO₂ emissions from energy-use data conditional on the assumption that CO₂ emissions are directly proportional to the quantity of an energy source consumed (Martin, 2012; Marin & Vona, 2019; Forslid et al., 2018; Barrows & Ollivier, 2018). At the firm level, firms report the total quantity of each energy source consumed each year (e.g., liters of diesel, Kwh of electricity, etc.). At the product level, firms report energy intensity of production by output product

– the amount of each energy source used to generate a single unit of the good. For both reports, we translate physical quantities of energy consumed into physical quantities of CO₂ emissions and sum over energy sources to compute firm-level or product-level emissions. Source specific emissions factors come from the US EPA 2012 Climate Registry Default Emissions Factors²⁵, and are reported in Table B.1. In the EPA report, CO₂ intensities are reported per unit of energy source (e.g., short ton of Lignite), and per mmBTU of energy. We use 25 energy sources and associated CO₂ emissions factors from Table 12.1 in the US EPA 2012 Climate Registry Default Emissions Factors, as well as the CO₂ factor for electricity generation in India reported in Table 14.4. The table reports 951 g CO₂ per Kwh for Indian electricity as the average intensity for grid electricity in the period 2000-2010.

In computing CO₂ emissions, several issues arise. We describe in detail each issue and our treatment of it in Barrows & Ollivier (2018), but mention them briefly again here. First, output units are not always the same across energy sources within the firm-year or firm-product-year. We standardize output units as much as possible, but must in the end drop observations for which standardization is not possible. Second, we are not able in every case to assign a meaningful CO₂ emissions factor to all energy reports. Emissions factors are reported for a specific unit of energy source consumed or mmBTU of energy. For a given energy source reported, if we can not convert the reported unit to match the unit in Table B.1, then we can not convert energy consumption into CO₂ emissions. We first attempt to standardize units, and then drop any observations for which we cannot match units with the EPA report. Third, we drop outputs which appear to be intermediate inputs used by the firm in later stages of production.

Table B.1: CO₂ emission factors

Energy Source	Kg CO ₂ per Unit of Energy Source	Unit of Energy Source	Kg CO ₂ per MMBTU of Energy Source
Acetylene	0.1053	scf	71.61
Agricultural Byproducts	974.9	short ton	118.17
Anthracite	2597.82	short ton	103.54
Biogas (Captured Methane)	0.0438	scf	52.07
Coke	2530.59	short ton	102.04
Coke Oven Gas	0.0281	scf	46.85
Distillate Fuel Oil No. 1	10.18	gallon	73.25
Distillate Fuel Oil No. 2	10.21	gallon	73.96
Electricity			278.00
Fuel Gas	0.0819	scf	59.00
Kerosene	10.15	gallon	75.20
Kraft Black Liquor	1131.11	short ton	94.42
LPG	5.79	gallon	62.98
Lignite	1369.28	short ton	96.36
Lubricants	10.69	gallon	74.27
Motor Gasoline	8.78	gallon	70.22
Naptha (<401 deg F)	8.5	gallon	68.02
Natural Gas (US average)	0.0545	scf	53.02
Petroleum Coke (Liquid)	14.64	gallon	102.41
Petroleum Coke (Solid)	3072.3	short ton	102.41
Propane (Liquid)	5.59	gallon	61.46
Residual Fuel Oil No. 6	11.27	gallon	75.10
Solid Byproducts	2725.32	short ton	105.51
Wastewater Treatment Biogas			52.07
Waxes	9.57	gallon	72.60
Wood and Wood Residuals	1442.64	short ton	93.80

Notes: The first column lists the energy source as named by the EPA. Prowess does not use exactly the same naming convention, so we mapped by hand these energy types to the energy types listed in Prowess. The second column reports kg CO₂ associated with a given unit of energy type in column 1, where the unit is reported in column 3. For most energy types, we use the CO₂ intensity listed in column 2. However, for some observations, we were unable to standardize units across the two datasets. In some cases, we were able to use an alternative CO₂ intensity reported per mmbTU. We list this alternative CO₂ intensity in column 4.

B.3 Merging Product-specific data to Output data

To compute firm-product-level emissions, we merge CO₂ emission intensity to product-level outputs. While there is no unique product-level identifying code on which to match, both energy intensity and product-level outputs report text descriptives of the products and CMIE has labeled products in both datasets with the 16-digit product codes. Hence, we could match either on exact string name or on the 16-digit product code. However, upon inspection, it seems clear that neither string names nor product codes are consistent across the two datasets.

Our strategy is first to match on exact string name of the product. Then, with all the products that fail to match on exact string name, we match by hand the inputs to the outputs based on the product descriptions. For example, in one case, a product described as “Shopping Bags/CarryBags” in the output dataset is merged to a product called “Plastic Bags” in the energy dataset. Though the names are not exactly the same, it seems clear from looking at the range of products described for the given firm that these two reports refer to the same outputs. By considering approximate matches such as this example, we increase the size of the matched input-output product-level dataset substantially.

B.4 Diagnostic checks of Product-specific Emissions Calculations

While firms are required by the 1988 Amendments to the Companies Act to report product-specific energy intensities, there are no formal mechanism to ensure accurate reporting. Additionally, there may be significant costs to breaking down energy use by product line for the firms. Hence, firms may not have strong incentives to report product-wise energy use accurately. Lacking independent audit reports of the energy-use data, we cannot say how accurate the reports are. However, we can perform diagnostic checks on the product-specific energy data and test alternative assumptions. We perform these tests in the appendix of Barrows & Ollivier (2018), but summarize them here.

Suppose that firms want to comply with the reporting requirement but do not want to pay the cost to learn how energy-use breaks down by product. Three reasonable hypothesis emerge. First, the firms could report pure noise for the energy intensity figures. If there is no penalty for false reporting and/or no mechanism for ensuring accurate reporting, then it is certainly possible that firms could follow this strategy. Second, firms might employ some cheap heuristic for determining product-specific energy use. The most obvious choice would be to break down energy use by sales share of the products. Sales share is not

difficult to calculate (and is in fact already required in the reports). So simply dividing total energy use by sales share would be a very cheap way to determine the product-wise energy intensity. Finally, firms might pick some value for energy intensity (either accurate or not) and report the same value every year. If firms followed the first or the third strategy, one would not expect the reported energy intensity to respond to foreign trade shocks, regardless of whether firms adjusted their technology.

To address these three hypothesis, we perform several tests in Barrows & Ollivier (2018). First, if firms report pure noise, then the computed emission intensity should not correlate with any variable. This hypothesis is easily rejected in Barrows & Ollivier (2018) by the strong correlation between emission intensity and product sales share rank within the firm. In Barrows & Ollivier (2018), we find that larger products have lower emission intensity. This relationship would be highly unlikely if the product-specific energy reports were pure noise.

Second, in Barrows & Ollivier (2018), we test for whether product-specific energy use is driven entirely by sales share. It is quite likely that higher-sales products should use more energy. However, if the energy reports are accurate, we would not expect sales share to explain all the variation in energy use. In Barrows & Ollivier (2018), we compute for each energy source (e.g., electricity, coal, diesel) the share of energy use devoted to a given product based on the product-specific energy reports. We then regress this variable on the sales share of the product within the firm-year. In Barrows & Ollivier (2018), we find that energy-use share is increasing in sales share, but that sales share does not perfectly predict energy-use share. To address measurement errors, we also instrument sales share with lagged sales share. In all specifications, we found point estimates away from 1. We take this as evidence that the product-specific energy data reflect more than just the sales share.

Finally, we can reject the hypothesis that firms do not adjust energy-use intensity year-to-year simply by noting the large amount of variation in emission intensities within product-line over time.

In summary, while we cannot say for sure how accurate the product-specific energy reports are without an audit, we test the three most obvious hypothesis for how the firms could misreport the information, and find compelling evidence against all three hypothesis.

B.5 Merging Trade Data to Prowess

To test for impacts of foreign demand, we must merge trade shocks to the product-level information in Prowess. International trade flows are classified in BACI according to the Harmonized System (HS) revision 1996, of which there are 5,132 6-digit codes (sections 1-21), while products in Prowess are classified according to CMIE’s own 16-digit coding system. Previous work has merged trade data to Prowess by first mapping HS codes to National Industrial Classification codes (NIC) via a crosswalk from Debroy & Santhanam (1993), and then to CMIE’s codes via a crosswalk provided by CMIE (see De Loecker et al. (2016) for an example). However, the cross-walk from Debroy & Santhanam (1993) is aggregated to the 3-digit level (for the most part), and relies on the version of the NIC from the early 1980s. Hoping to exploit differential growth rates in foreign demand at a more granular level, we construct our own cross-walk between the CMIE product codes and HS revision 1996.

We aim to assign one or more HS codes to each of 3,324 distinct 16-digit CMIE product codes based on the descriptions of the products. While descriptions in the two datasets are usually not exactly the same, both classifications hew fairly closely to the ISIC classification, which means that product ordering and text descriptions are often quite similar in the two datasets. We thus match HS codes to CMIE product codes by hand as follows.

We first attempt to match one or multiple 6-digit HS codes to a given 16-digit CMIE product code. Sometimes, there is no obvious 6-digit match. In these cases, we exploit the fact that the HS follows a tree-like structure, so that all products with the same first four digits belong to a common family of products. Thus, while there may be no 6-digit code that matches to a 16-digit CMIE code, there may be a 4-digit HS code. Finally, if no 4-digit code can be matched to a CMIE code, we match to the 2-digit HS code. See Table B.2 for an example. Here, one can see that some CMIE products match to 6-digit HS codes, while other products can only be matched to the broader 4-digit group. In the full crosswalk, we match 3,276 distinct product codes to at least a 2-digit HS code.

Next, we translate foreign demand computed for 6-digit HS codes in BACI into 16-digit CMIE codes. When a single 6-digit HS code matches to a 16-digit CMIE code, then translating between the two classification systems is simple. However, as is illustrated in Table B.2, in some cases, multiple 6-digit codes match to the same 16-digit CMIE code, and sometimes CMIE codes only match to a 4-digit or even 2-digit HS code. In these cases, we must take averages over shocks computed at the 6-digit level.

Index 6-digit HS codes by $h6$, 4-digit HS codes by $h4$, 2-digit HS codes by $h2$, and 16-

digit CMIE codes by c . Foreign demand and instruments $FD_{h6,t}$ and $Z_{h6,t}$ are computed in Section 2.2. Suppose that a given CMIE product c matches to multiple 6-digit HS codes. This could be because the CMIE code is less detailed than the 6-digit HS codes, or because there is uncertainty with respect to which 6-digit HS code best describes the CMIE product code. To assign a foreign demand in this case, we take a simple average over shocks computed at the 6-digit level:

$$\Theta_{c,t} = \sum_{h6 \in \Delta_c} \Theta_{h6,t} \quad (\text{B.1})$$

for each $\Theta \in \{FD, Z\}$ and each $h6$ that matches to the CMIE code c .

Next, suppose we cannot match any 6-digit codes to a CMIE code, but can match an entire 4-digit category. In this case, we simply take the simple average of foreign demand and instruments over all 6-digit codes in the 4-digit code:

$$\Theta_{c,t} = \sum_{h6 \in \Delta_{h4}} \Theta_{h6,t} \quad (\text{B.2})$$

for each $\Theta \in \{FD, Z\}$ and each $h6$ in the aggregate $h4$. Then, if multiple 4-digit codes match to a CMIE code, we again take a simple average over the 4-digit codes

$$\Theta_{c,t} = \sum_{h4 \in \Delta_c} \Theta_{h4,t} \quad (\text{B.3})$$

We then follow the same procedure to compute shocks for CMIE codes that match to 2-digit HS codes.

In an abuse of notation, in the main text we refer to both BACI codes and CMIE codes as j , though in reality when considering shocks computed in the CMIE coding system, a product j potentially refers to simple averages over multiple 2-digit, 4-digit, or 6-digit HS codes.

Table B.2: Cross-Walk Example

4-Digit HS Desc	HS4 Code	6-Digit HS Desc	HS6 Code	CMIE Desc	CMIE Code
Synthetic filament yarn, not put up for retail sale	5402			Synthetic filament yarn other than sewing threads	0605010200000000
		High tenacity yarn of nylon or other polyamides	540210	High tenacity yarn of nylon or other polyamides	0605010201000000
		Tyre cord fabric	590210	Nylon tyre yarn	0605010201000999
		Of nylon or other polyamides			
		Other yarn, single, untwisted or w/twist not exc. 50 turns per	540241	Nylon filament yarn	0605010201020000
		Of nylon or other polyamides			
Synthetic filament yarn, not put up for retail sale	5402			Yarn of other polyamides , excluding nylon	0605010201030000
		High tenacity yarn of polyesters	540220	High tenacity yarn of polyesters	0605010202000000
Synthetic filament yarn, not put up for retail sale	5402			Polyester filament yarn (PFY)	0605010202000999
Synthetic filament yarn, not put up for retail sale	5402			Other polyester, excluding terylene dacron	0605010202019999
Synthetic filament yarn, not put up for retail sale	5402			Partially oriented yarn (POY)	0605010202040000
Synthetic filament yarn, not put up for retail sale	5402			Drawn textured yarn (DTY)	0605010202060000
		Textured yarn :- Other	540239	Textured yarn of synthetic filament yarn	0605010203000000
Synthetic filament yarn, not put up for retail sale	5402			Other synthetic filament yarns	0605010204000000
Synthetic filament yarn, not put up for retail sale	5402			Polyvinyl acetate filament yarn	0605010204009999
Synthetic filament yarn, not put up for retail sale	5402			Polyvinyl chloride filament yarn	0605010204019999
Synthetic filament yarn, not put up for retail sale	5402			Polypropylene filament yarn (PPFY)	0605010204030000
Synthetic filament yarn, not put up for retail sale	5402			Acrylic filament yarn (AFY)	0605010204040000
